**Address in Medicine.**—This was delivered by Dr. J. A. Witherspoon, of Nashville, Tenn. He selected for his subject typhoid fever. In this day of progressive medicine, when the whole profession were anxious to elucidate the etiology of disease and its prevention, no field had been so thoroughly gone over, and no trials or hardships had been so difficult as the study of the plain, old-fashioned disease—typhoid fever. While the laboratories with their facilities for studying pathogenic micro-organisms, developed in the last few years, had made wonderful progress, the speaker belonged to that school which believed that, while the diagnosis should be made with the assistance of the bacteriologist, more importance should be attached to making it clinically at the bedside. In other words, the speaker was absolutely opposed to doing away with the good, old-fashioned methods of examining the patient, and to relegating the system of the fathers to the rear and making diagnoses purely in the laboratory. Typhoid fever was a specific toxæmia, it being produced by the typho-toxins elaborated in the system from the bacillus of Eberth. The speaker then dwelt at length upon the differential diagnosis of typhoid fever and what he called toxo-enteric fever. In speaking of the treatment of these diseases, he stated that the man had never lived who could get up prescription number one and formula number two, etc., have them made in Detroit or any other city, and tell him how to treat a case of typhoid fever in the active stage of the disease. He was unalterably opposed to any man putting up prescriptions for him.

**Obstructive Growths of the Pylorus.**—This was the title of a paper by Dr. J. E. Allaben, of Rockford, Ill., in which the author reported a successful and interesting case of pylorectomy, after which he drew the following deductions: (1) Cancer was one of the most potent factors in the causation of death, with a tendency to increase constantly in frequency of occurrence. (2) Gastric cancer occurred in about one-fifth of all primary cases. (3) In gastric cancer the pyloric region was affected in sixty per cent. of the cases. (4) The treatment of gastric cancer directed toward a permanent cure was, in the present state of our knowledge, limited wholly to surgical methods. (5) As early total extirpation of malignant growths with the hope of permanent cure was the goal toward which we were constantly striving, and as these growths in gastric cancer occurred at the pyloric region in sixty per cent. of the cases, it would seem to follow as a natural conclusion that pylorectomy would be the treatment most frequently prescribed for the cure of this malady. (6) Inasmuch as early diagnosis was the greatest requisite for directing proper radical treatment, the internalist and the surgeon should turn their best efforts in this direction. (7) If the operation of pylorectomy was performed before obstructive symptoms manifested themselves, and before the occurrence of metastasis, the immediate results would be as favorable as in any other abdominal work, and the remote results as good as in extirpation of carcinoma of the breast.

Dr. J. L. Boogher, of St. Louis, Mo., read a paper in which he dwelt principally upon the value of prostatic examination in the treatment of associated affections.

**What Becomes of the Medicinally Treated Cases of Appendicitis?**—This paper was read by Dr. Lewis Schooler, of Des Moines, Ia. The author predicted that the facts, as disclosed by greater observation and the increasing experience of medical practitioners, would inevitably show that the present position occupied by them was untenable. Patients who were treated only by means of medicine either died under such treatment or were later cured by operation. To the above there should be noted a single exception, namely, those cases which were spontaneously cured. This occurred by rupture into the bowel, vagina, bladder, or externally. Instances of this method of cure were familiar to all. It was therefore singular that, in view of such familiar occurrences, medical gentlemen did not take the hint that nature was so persistently urging upon them, and comprehended more clearly the fact that removal of the offending cause, organ and product, was the only rational procedure. It was the only one that was approved by nature, pathology, observation, and science.

Dr. Hal C. Wyman, of Detroit, Mich., followed with a paper in which he dwelt upon the surgical features of appendicitis.

In the discussion, Dr. J. A. Allaben, of Rockford, cited a case which showed the folly of delay in surgical intervention.

Dr. F. F. Bryan, of Georgetown, Ky., narrated four cases which emphasized the points brought out by the essayists.

Dr. J. O. Malsbury, of Peru, Ind., referred to the importance of more careful diagnosis on the part of internalists, so that cases suitable for operation should be referred to the surgeon without delay. He classified cases of appendicitis as inflammatory and mechanical.

Dr. N. Mover, of Chicago, said that he formerly regarded this disease as a surgical one, and that when a case was diagnosticated as such it should at once go to the surgeon. He believed now that many cases belonged to the internalist. Indiscriminate operations, in his opinion, for appendicitis were followed by a greater mortality than occurred in those cases treated medically.

Dr. J. N. Bartholomew, of Chicago, said he looked upon appendicitis as a surgical affection from beginning to end, and as the result of germ infection. He favored early operative intervention.

Dr. C. K. Brunner, of Greenfield, Ind., was firmly convinced that he saw many cases of appendicitis that never became surgical, and these, when properly treated medically, resulted in recovery.

Dr. J. Humphrey, of Henderson, Ky., said that the surgeon and physician should work hand-in-hand in cases of this disease. They should discriminate between medical and surgical cases.

Dr. T. A. Lancaster, of North Manchester, Ind., quoted the opinions of Keen, Morris, and others in regard to this disease, and said they were undergoing material changes, in that these men were not operating so hastily as they had been doing heretofore.

Dr. V. J. Hawkins, of St. Paul, Minn., said he thought many cases of the disease could be treated medically, while others required operation.

The discussion was further participated in by Drs. Charles B. Brown, of Sycamore, Ill.; R. E. Haughton, of Richmond, Ind.; J. Henry Carstens, of Detroit, Mich.; S. K. Crawford, of Chicago; James B. Bullitt, of Louisville, Ky.; A. H. Cordier, of Kansas City, Mo.; Frederick C. Schaefer, of Chicago; Emory Lanphear, of St. Louis. The discussion was closed by the essayists.

**Intestinal Obstruction from Biliary Calculi.**—Dr. J. Wesley Bovee, of Washington, D. C., read a paper with this title, in which he stated that intestinal obstruction from biliary calculi was very uncommon. Brinton found in five hundred cases of intestinal obstruction but twenty-four due to gall stones, and Leichtenstern found but forty-one in fifteen hundred and forty-four cases of bowel occlusion. In Manchester Royal Infirmary but one case in fifty thousand patients treated for all troubles was found. As it was a condition practically limited to late life, its rarity was to be expected. The author then dwelt upon the varieties of obstruction, the location, causes, symptoms, and prognosis. In considering the treatment he stated that Hippocrates and later others recommended the injection of air into the bowel. Tobacco smoke and infusion and different gases had been thus employed. Purgatives were positively harmful. Morphine and belladonna were the best two drugs for use in this condition. Of couse, electricity had not been omitted. With medical treatment nearly half the patients recovered, but was that a sufficiently large proportion? In 1672 Barbette recommended laparotomy for acute intestinal obstruction, and as abdominal surgery was now practised its use in acute obstruction of the bowel from biliary calculi should give brilliant results. Medical treatment might be used for a short time, and, failing, should be superseded by laparotomy, with a careful exploration of the abdominal and pelvic contents. The seat of obstruction being found, the condition of the patient and the degree of mobility of the stone in the bowel would guide the operator in the subsequent steps. The plan of Tait, of passing a strong needle obliquely through the bowel wall into the stone to break it up, might first be tried, the puncture wound being closed by a Lembert stitch. This failing, the stone should, if possible, be pushed higher in the bowel and a longitudinal enterotomy be done with extraction of the stone. Gangrenous bowel, perforation, or localized peritonitis, with or without pus, should be treated *secundum artem*. It was always well to look for a second obstruction, as this had caused death in some cases. The deaths following laparatomy for this condition were nearly always from shock or sepsis, which was a strong argument for early operation. It would not seem improbable that early laparotomy in these cases should have a mortality of less than ten per cent.

**Address in Surgery.**—This was delivered by Dr. Lewis S. McMurtry, of Louisville, Ky. He selected for his subject "The Essential Requirements of a Modern Operative Procedure." In the past fifteen years the province of surgery and its scope had been greatly enlarged. Many diseases and injuries that were formerly treated on the expectant plan and by palliative measures, with little hope of permanent relief or cure, were now cured by judicious surgical intervention. Notwithstanding the increase in hospital facilities in cities and towns, many important surgical cases must receive immediate attention at the hands of the family physician, from the very nature and urgency of the disease or accident. Such cases were classified as emergencies, and they included many major as well as minor injuries. When a major or minor surgical operation was to be done, certain fundamental principles of asepsis should be observed, and yet it was comparatively exceptional in private homes for minor surgical procedures to be carried out without the presence of pus following the operation. The speaker said that there were three important steps to be observed. The first was the administration of the anæsthetic. This required skill, which could be acquired only by practice; hence medical students should receive practical instruction in the administration of anæsthetics. The second element of a surgical procedure consisted in the control of hemorrhage. In the early days of abdominal surgery it was common to disregard the question of hemorrhage. All those present would remember the days when the drainage tube was more frequently used than it was now, and that within forty-eight hours after an operation it was customary to pump out considerable quantities of blood as the result of oozing from small vessels that were ignored in the operation. Nowadays, when more attention is given to hæmostasis, hemorrhage was lessened on account of attention being directed to the small vessels. A third indication, and one to which the speaker devoted the remainder of his remarks, was the important one of asepsis.

**Treatment of Nasal Stenosis due to Deflections of the Nasal Septum, With or Without Thickening of the Convex Side.**—Dr. John J. Kyle, of Indianapolis, Ind., read a paper on this subject. In his opinion the most frequent cause of deflection was trauma. Ulceration of the septum or inflammation within it, as noted in a child suffering with congenital syphilis, and hypertrophy of the turbinates, were causative factors. A strumous or uric-acid diathesis might predispose to perichondritis and subsequent deflection. The author showed different forms of deflection, by passing around diagrams. Speaking of the surgical treatment, he mentioned the operation of Asch as being the most popular, and said he believed it would bring about a positive result.

**Removal of the Cervical Sympathetic for Epilepsy, Exophthalmic Goitre, and Glaucoma.**—Dr. Emory Lanphear, of St. Louis, Mo., contributed this paper. He mentioned the work of Jonnesco and other surgeons along this line, saying that this field of surgery was worthy of further study and investigation.

**Surgery of the Turbinated Bones.**—The author of this paper was Dr. J. A. Stucky, Lexington, Ky. He did not discuss operative procedures on the turbinated bodies, nor on any of the soft tissues covering the bone, but rather the bone itself. While it was true that the tissues covering the bone were far more frequently found in a pathological condition and required surgical treatment, it was was also true that the bone itself in many instances was at fault. When this was the case, the mucous membrane and turbinated bodies might be entirely obliterated by chemical and electric cautery, or by scissors, forceps, and snare, and the latter condition of the patient would be worse than the former, because of the remaining cicatricial tissue and unnatural dryness of the parts. Dr. Stucky then called attention to what he considered the best method of removing a part or whole of the bone. The first and most important desideratum in all intranasal operations was to remove only just as much tissue as was absolutely necessary.

The crushing or punch forceps, spoke-shave, and snare should be used only in exceptional cases. In removing a part or whole of the middle turbinate, correctly shaped scissors were the only instrument needed. For this purpose he had found none equal to those devised by Dr. C. R. Holmes, of Cincinnati, one for each turbinate, right and left. For turbinectomy or turbinotomy of the lower bone, the narrow-bladed scalpel, saw, and strong, straight scissors were needed. An incision through the soft tissues was made along the edge of the bone, this was peeled back with the back of the scalpel, and the bone exposed. Should this be too firm to be cut with the scissors, a narrow, thin saw was used. In cases in which the knife, saw, and scissors could not be used to complete the operation on account of the size, depth, and conformation of the nasal chambers, the snare was used to complete the removal of the posterior portion. Little or no dressing was needed after the operation, except when the lower turbinate had been entirely removed; then strips of gauze placed smoothly over the wound were allowed to remain twenty-four or thirty-six hours, and then carefully removed, after thoroughly softening with fifty per cent. hydrogen dioxide. The subsequent treatment consisted of keeping the parts clean until union was complete.

**Mammoth Ovarian Tumors: Report of a Cyst Weighing Two Hundred and Forty-Five Pounds.**—This was the title of a paper read by Dr. James B. Bullitt, of Louisville. Only growths weighing one hundred pounds or more had been regarded as mammoth tumors. A search through literature had developed reports of twenty-three such tumors. Brief summaries of these cases were given. The largest of the tumors weighed two hundred and two pounds. The essayist added a twenty-fourth case by reporting in detail the case operated on by Dr. A. M. Cartledge, of Louisville, in May, 1897. The tumor, sac, and contents together weighed two hundred and forty-five pounds. There were a great many adhesions encountered, and the operation was prolonged. The woman rallied from the shock and was in good condition at the end of five days, when obstruction of the bowel became manifest, the patient dying on the seventh day. In considering the twenty-four cases it was observed that twenty-one cases were operated upon. Of the fifteen in which recovery took place the average tumor weight was one hundred and twenty-nine pounds; while of the six in which operation was followed by death the average weight was one hundred and eighty-one pounds. There were manifestly but three methods of dealing with these tumors: (1) Immediate extirpation, (2) preliminary tapping followed in a short time by extirpation, (3) tapping repeated as often as necessary to relieve uncomfortable distention. To illustrate that life may be long sustained by constant tapping and withdrawal of fluid, the case of Dr. Ap. M. Vance was cited, in which the woman was tapped one hundred and seventy-nine times between the ages of thirty-four and eighty years, it being computed that in this time twenty-one thousand four hundred and eighty pounds of fluid were withdrawn. In so far as any conclusions could be drawn from the study of these twenty-four cases the following were submitted: (1) The fatality from such tumors was directly proportioned to the size of the tumor. (2) Extensive adhesions to the parietes and viscera militated against successful operations, but were second in importance to the size of the tumor. (3) Preliminary aspiration followed by extirpation in a few days was apparently no safer than immediate operation. (4) Marsupialization was contraindicated in tumors of mammoth proportions. (5) Successive tappings were sometimes tolerated over a long period of years, but led ordinarily to exhaustion and death in a comparatively short time, a few years. (6) When death occurred after operation it was most apt to be immediate, or within a few hours, as the result of shock. If this first danger was passed safely, the fatal issue was apt to be the result of obstruction of the bowel, especially in those cases in which extensive adhesions were present.

Dr. A. H. Cordier, of Kansas City, Mo., mentioned the case of a woman, colored, forty-three years of age, who had carried an ovarian cyst for eleven years. The cyst with its contents weighed one hundred and sixty pounds. The patient died on the ninth day following the operation, from exhaustion.

Dr. S. L. Kilmer, of South Bend, Ind., reported an interesting and instructive case of an arm saved after being run over by a railroad locomotive and badly crushed. The case was cited as a plea for greater conservatism in such injuries.

Dr. George W. Crile, of Cleveland, Ohio, followed with a paper in which he detailed his observations on the surgery of the brain, which were based on clinical and experimental evidence.

**Obstipation and Its Radical Treatment.**—Dr. Thomas Charles Martin, of Cleveland, Ohio, read a paper with this title. He said that the rectal valve was an individual anatomic organ in itself, and must now be reckoned with in studying the operations of the integral mechanism of defecation. When the muscular elements were relaxed and the gut was either greatly dilated or else was even in a lesser measure distended, the valve was passively supported by its fibrous band across the channel to resist the hurried or uncontrolled descent of the fæces. The presence of the band of fibrous tissue under the free margin of the valve provided a control to receive or retain a bolus, or it may be said the several valves received a series of boluses till a sufficient pressure was made to stimulate the complex involuntary mechanism of defecation to further propulsion of the fæces, or to a reversed peristalsis. The presence of the fæces or the involuntary movements incident to their presence signalled the consciousness to co-operative voluntary expulsory effort, or gave warning of the necessity of voluntary resistance. The valvular arrangement of the rectum provided for the minimum expenditure of energy on the part of the voluntary forces, for the reason that the gut's contents were collected on the surface of the unyielding sacrum and steadied there to receive the pressure of the really expulsory voluntary effort. Such an arrangement of the fæces further facilitated defecation for the reason that the entire contents of the rectum were not rushed upon the anus at once. If it was the function of the normal rectal valve to retard beneficently the descent of the fæces, it was obviously true that it might be the especial property of the valve, in certain other than normal conditions, to obstruct maliciously the descent of the fæces. The symptoms of obstipation were the following: The patient was the subject of more or less chronic irregularity of defecation. He on some days made frequent partially successful attempts to evacuate the rectum, but might experience an unrequited desire for stool. The patient acquired the reprehensible physic habit. In time the periods of obstipation were interrupted by diarrhœa. There was commonly an ineffectual straining at stool except for fluid fæces. The writer described a method for division of the obstructing valve, and presented cases.

Dr. James T. Jelks, of Hot Springs, Ark., reported a unique case of appendicitis, and made some remarks on the treatment of this affection.

Dr. I. N. Love, of St. Louis, read a paper on the same subject from a medical standpoint.

Both papers were discussed at length, but nothing new was advanced.

Dr. Augustus Schachner, of Louisville, read a paper on the modern small-bore projectile.

**Surgical Tolerance and Results.**—This paper was read by Dr. F. F. Bryan, of Georgetown, Ky. The essayist concluded that tolerance was due (1) to individuality of the subject; (2) to the vital resistance furnished by organs capable of performing their functions; (3) by the immediate necessity for the part by the body as a whole, for the aid of the part operated upon, in carrying on life; (4) by preventing or limiting shock; (5) by limiting hemorrhage; (6) by preventing or limiting sepsis and removing the same. Results will depend on: (*a*) Refusing operation to a hopeless class of patients; (*b*) by painstaking care to make the procedure thorough; (*c*) by demanding sufficient time for thorough convalescence and adaptation of the patient to the changes that have been wrought.

The following officers were elected for the ensuing year: *President*, Dr. Harold N. Moyer, of Chicago; *Vice-Presidents*, Drs. A. H. Cordier, of Kansas City, Mo., and S. P. Collins, of Hot Springs, Ark.; *Secretary*, Dr. Henry E. Tuley, of Louisville, Ky.; *Treasurer*, Dr. Dudley S. Reynolds, of Louisville.

The next place of meeting will be Asheville, N. C., on October 4, 1900.

---

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

BRITISH ASSOCIATION—TYPHOID OUTBREAKS—AUTUMNAL DIARRHŒA—MANCHESTER MEDICAL GUILD—DEFYING THE LOCAL GOVERNMENT BOARD—DEATHS OF MESSRS. LITHGOW, BUDD, AND KEIGHLEY.

London, September 22, 1899.

The British Association has completed its annual output of papers and speeches, and the members have dispersed. A memorable feature of this year's gathering has been the interchange of civilities between this and the French association, which may be thought the most interesting of the daughter societies. The Frenchmen came over in force to meet us on Wednesday at Canterbury, and gave every indication that they enjoyed the visit. I am sorry to say their pleasure must have been discounted by the unpleasant experience of their return voyage. Their steamer was damaged in a storm, and they had a terrible crossing of the Channel. At Boulogne there was difficulty again, and they were not landed until three o'clock yesterday morning.

Far more fortunate were the members of the British Association, who to the number of about two hundred and fifty went yesterday to Boulogne and were warmly received by the French association. At luncheon the mayor dwelt on the reunion as representing the co-operation of Anglo-Saxon, Celt, and Gaul in the service of science and humanity. M. Brouardel in his speech ventured the calculation that Lord Lister's work had saved two hundred thousand lives.

Special commemoration medals were presented by the French association to the mayor of Boulogne and Sir Michael Foster. In the afternoon a monument was unveiled to Dr. Duchesne, and also a plaque commemorative of our poet, Thomas Campbell, who died at Boulogne.

The meeting for next year is to be held at Bradford, and the president-elect is Sir William Turner.

Typhoid seems always with us in some form. If not close at hand we are sure to hear of an outbreak somewhere not far off. I have lately reported some of these. I may add another at Ashford, Kent, in a range of cottages by the side of the river (Stour), which should cause the local authorities to question themselves. There is another in Buck's, at High Wycombe, a town of fifteen thousand inhabitants about thirty-five miles from London, and named "High" perhaps on the *lucus a non lucendo* principle, for it is quite down in its valley. More than twenty notifications were made in a short time, and the medical officer of health at once reported to the town council his recommendations. The cases are mostly in a locality inviting the disease by water. There are open gullies near the cottages, where all sorts of pollution occur, and where the children will drink when thirsty in spite of parental warning. Parasites are therefore pretty sure to attack them, and there is always the chance of the typhoid poison being conveyed.

The mortality returns are showing the extent of the prevalence of autumnal diarrhœa. The usual seasonal increase of this disease has been above the average, and London has had a full share of its incidence. There is more than the average among adults, although, of course, children have suffered most. The aged, too, are numerous among the victims. The long drought has had its effect on the water supply, which no doubt is to some extent responsible and requires as much vigilance as the milk supply. But the great heat has probably been a more active general cause, though water or milk will account for more localized outbreaks.

The Manchester Medical Guild proposes an important step toward the organization of the profession, viz., a conference of delegates elected *ad hoc* by all the associations of general practitioners in the kingdom. Each delegate would thus represent a number of his fellows, and although at first the conference, or at any rate the preliminaries for it, must be organized locally, the intention is for it to be national in character and extent. If the suggestion "catches on," and the conference meets, it will be further proposed by the Guild for it to elect a central committee whose business it would be to perpetuate the work and perfect the organization of the profession. There would follow, I suppose, an annual conference to deal with the many questions affecting the interests of the profession or at any rate of the general practitioners, and as these constitute the masses it is well they should have a voice in a society where the classes would not overwhelm them. Scientific and even clinical discussions must consequently be excluded, but we have a plethora of associations for them. This scheme is therefore distinctive, and may perhaps become effective, but when one looks back on the many efforts at organization which have failed the prospect is none too exhilarating.

As an objection the cry is sure to be raised in some quarters that it is an invitation of trades unions. But if so, what then? Is it not still laudable to learn from the enemy; and why should Satan have all the best tunes?

The St. Olive's district board is contumacious, and on the 19th inst. resolved: "That the local government board be informed that this board declines to remove the suspension of the medical officer of health (Dr. Bond), and again asks the local government board to hold a public inquiry into the whole matter." You will remember the matter relates to the removal of human remains from the crypt of a church, done according to law by the bishop with the aid of the medical officer. The next move is for the local government board. Will it suffer open defiance as in the case of anti-vacs?

*The Medical Press and Circular* claims to have originated the phrase "stamp-lickers' tongue," and says it "was created and evolved in our own office and thence issued to the world at large." It appears, too, that the

"world at large" has appropriated this creation and evolution, for your contemporary adds: "The phrase has evidently taken a place in the English language, for last week we saw it in a prominent position in one of the London daily newspapers, to wit, *The Daily Chronicle*." I should scarcely have set up *The Chronicle* as a standard of literary taste; but let that pass. *The Press and Circular* has enriched the English language with such an elegant phrase! *Palmam qui meruit ferat.*

The deaths are announced of: Surgeon-Major S. A. Lithgow, C.B., on the 20th inst., aged sixty-six years. He had a distinguished career in the army, and in 1892 occupied the position of medical superintendent of the Edinburgh Royal Infirmary. S. P. Budd, M.R.C.S., of Bath. He was one of a family of the West of England which has had many distinguished doctors in its number for many years past. He died on the 11th inst., aged fifty-five years, of malignant disease. He was much esteemed by his brethren. Robert D. Keighley, J.P., consulting surgeon of the Batler Hospital, in his eightieth year.

## THE TREATMENT OF TYPHOID FEVER.

To the Editor of the Medical Record.

Sir: The Medical Record for September 16th publishes a paper from the pen of Dr. Basil M. Taylor, who attempts to instruct the many readers of the Record how to treat, or not to treat, typhoid fever. The young man—who says he has practised medicine seven years—prefaces his remarks with the statement that we know little or nothing about treating typhoid fever, though much has been written on this disease. If his thesis were to be taken as a fair representative of what had been said before, we should most fully agree with the young doctor. He starts out by telling us that typhoid fever is a self-limited disease which we cannot abort or even cure. Then, we ask, must we pretend to treat it so as to get a fee to which we are in no way entitled? But the doctor goes on and tells us many things; among them, not to give stimulants, whiskey, quinine, etc. He also tells us to give nourishment three times daily only, and if the stomach is nauseated stop all food for twenty-four hours. He says: "Don't give milk; don't stimulate a weak heart in any case." We do not at all wonder that he lost several patients, whose taking off was due, he says, to bad nursing. Of course starvation and lack of stimulation in typhoid fever did no wrong; it was the nurse who was to blame for this sudden taking away. The doctor claims that some of his patients who had typhoid fever actually got well; which is another exemplification of the old saw, that some patients will get well in spite of the disease and the doctor. This doctor in one instance—though he objects to stimulants; he probably did not know it would stimulate—came very near recommending a very good remedy in typhoid fever. This was when he said, give turpentine in a capsule; a little acts very well, as do bismuth, carbolic acid, and chloral. A doctor who objects to milk in typhoid fever and prescribes chloral should go back to his preceptor awhile. We presume the doctor never heard that turpentine should be given in an emollient, and when given thus it is a stimulant antiseptic and is healing to the ulcerating Peyer's glands, and is therefore an excellent remedy in typhoid fever and pneumonia also.

We have practised medicine only about thirty years and do not claim to be as well posted as many of our older practitioners who have had greater experience. But in the treatment of typhoid fever we in some instances gave cathartics—which Dr. Taylor says never give—and our patients got well. In other cases we did not use cathartics, and these patients got well also. Our sheet-anchor in typhoid fever always has been good, judicious feeding, with antiseptics, sedatives, and stimulants when the heart was weak—brandy usually, especially so when there was delirium. We prescribe hot milk for food, and if not relished by the patient we give it cold sometimes; for obvious reasons we add a little lime-water to the milk; and the nurses do not cause the death of our patients, as the latter get well in ninety-eight per cent. of the cases. We do not remember ever having seen hemorrhage from the bowels of one of our patients when we had used a good emulsion of turpentine from the start. In typhoid we usually give five to six drops of turpentine to the drachm of emollient once in three to four hours, as the case may in our judgment demand. Again, the doctor in his thesis appears to think that a coating of the tongue is absolutely necessary in typhoid fever. In the severest cases of this disease we ever treated the patients had a smooth, dark red tongue. This showed to us a critical condition indicating an arrest of function of both stomach and small intestines, requiring dilute muriatic acid with quinine, and turpentine inunctions over the stomach, and small doses of strychnine for a stimulant to the nervous system. Again, we have the rough, red tongue demanding the mineral acids also; and again the dark-brown coated tongue with black sordes on the teeth calls for the acid treatment. The tongue in nearly every instance in typhoid is red and demands acids, yet we have cases in which in the beginning the alkalies are the proper antidote; the tongue being light in color with a dirty, sticky coloring indicating sulphites of soda as the remedy. The condition of the mucous membranes and the pulsation of the heart are the best guides to treatment. We never give quinine unless the skin is moist, but with a moist tongue and skin the cinchona extracts are good. We have no uniform mode of treating typhoid. We treat conditions as they indicate the antidote, etc. But there are some general rules that cannot be safely omitted in any case of typhoid, and stimulation is one of them.

Floyd Clendenen, M.D.

La Salle, Ill.

## THE CONVERSION OF CENTIGRADE TO FAHRENHEIT.

To the Editor of the Medical Record.

Sir: I wish to call the attention of the profession to a simplification of the "Rules for converting degrees Centigrade into degrees Fahrenheit and the reverse." Every one realizes that it takes time to do this example after the usual method. For fifteen years I have used the following method for converting from one scale to the other. The operation is mental and requires no consideration of the freezing-point of water, or 0° F.

For converting F. into C. (mentally) subtract 32; to the result add $\frac{1}{9}$ of this remainder; divide this sum by 2, as per following formula: F. $- 32 + \frac{1}{9} \div 2 =$ C. Example: 212° F. $- 32 + 20 \div 2 = 100°$ C. For converting C. into F. multiply by 2, subtract $\frac{1}{10}$, add 32, as per following formula: C. $\times 2 - \frac{1}{10} + 32 =$ F. Example: 100° C. $\times 2 - 20 + 32 = 212°$ F.

A. M. Whiton, M.D.

South Byron, N. Y.

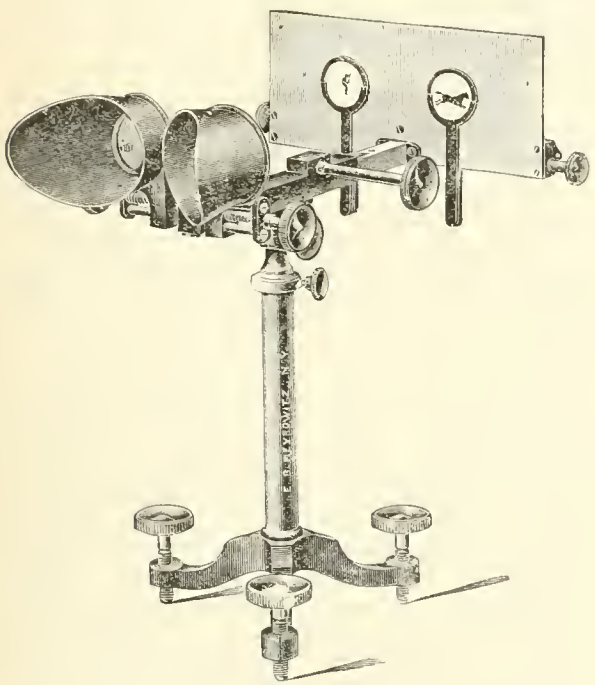
**Fistula in Ano and Phthisis.**—In incipient phthisis, operate; in rapid progressing fistula, operate whether cough exists or not; if much cough exists, do not operate unless the fistula is rapidly progressive; in the last stages of phthisis, do not operate.—Matthews.

# New Instruments.

## MODIFICATION OF THE STEREOSCOPE.[1]

By RICHARD H DERBY, M.D,
NEW YORK

The usefulness of the stereoscope in the exercise of the ocular muscles has been recognized by many writers. Albrecht von Graefe used in the ordinary Holmes stereoscope a card divided by vertical and horizontal lines into regular spaces. Broad-headed brass pins, such as draughtsmen use, were substituted



for the half pictures, and the position of these pins was changed according to the needs of the internal and external recti muscles. This device was resorted to constantly after tenotomy, and it was an aphorism of von Graefe that the mathematical proof of a successful squint operation was the establishment of stereoscopic vision. The ingenious cards of Dr. John Green,[2] the series of Kroll and Perlia,[3] those of Dahlfeld,[4] and more recently those of Javal,[5] all served a like purpose. The Javal cards presented the half-pictures in a series of increasing distance from the middle line, in the interest of faulty convergence and divergence.

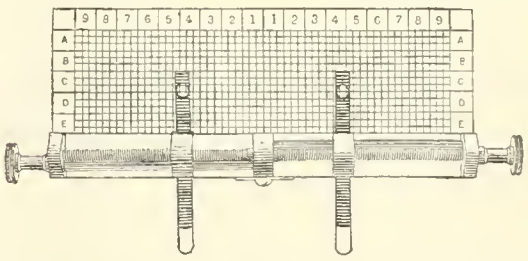
The writer of the present paper long felt the need of some mechanical device, by means of which the half-pictures could be readily displaced upon the surface of a fixed card, and this not alone in a horizontal but in a vertical direction. To attain this end the present instrument was devised, and some description of its earlier form was published in the Transactions of the New York Eye and Ear Infirmary.[6] Since this publication certain changes have been made, and the author believes that in its present form it possesses advantages over other instruments now in use.

To meet varying pupillary distance the convex prisms in the eyepiece may be separated or approached by means of a screw at the will of the patient, frames being provided to carry both spherical and cylindrical lenses. The object card, made of metal, is placed on a firm shaft, and by a screw adjustment may be moved to any required distance from the eyes of the patient. On the back of this card vertical and horizontal lines have been engraved, at a distance of 1 cm. the one from the other. The horizontal interspaces are marked by letters of the alphabet and the vertical by numbers. Along the lower margin of the object card an endless screw moves the carrier of the half-pictures in either the lateral or vertical direction, and its position may be read and recorded through an opening in the back of the carrier, on the engraved object card. In the case of eyes where there is dynamical equilibrium, the centre of the half-pictures is ordinarily 4.5 cm each from the middle line, and they are centred on the same horizontal line. Should the patient, in order to obtain stereoscopic vision, turn the screw and place one half picture higher than the other, insufficiency of superior or inferior rectus or of an oblique muscle is indicated. In the same way if the half-pictures are approached to a distance of 3.5 cm. or separated to a distance of 5.5 cm., insufficiency of externi or interni respectively may be inferred.

It is, however, not alone as an instrument for the detection of muscular imbalance that the stereoscope has yielded to the writer the best results. In orthoptic exercise much advantage may be gained from the use. While it would be too much to claim that with it alone strabismus, either real or dynamical, can be relieved, still experience has shown that systematic exercise with it is most advantageous in both classes of cases.

The following notes from the author's case-book illustrate the range of usefulness of the instrument:

Case I.—Paresis of external rectus. Mrs. E. D——, aged forty years. The day before the patient was seen, she awoke with a distressing diplopia. There was a nearly complete paresis of the left external rectus. Refraction was normal. With the stereoscope only the closest possible approximation of the half-pictures gave binocular vision, and then only for a moment Daily stereoscopic exercise was enjoined. The half-pictures were gradually brought farther and farther apart until within ten days they could be seen at the normal distance of 4.5 cm. So soon as the paretic externus began to regain its tone, the patient received the series of Kroll's cards for use at home, and they in turn were gradually mastered. The ordinary period of convalescence seemed here to be materially



shortened, and the patient derived much encouragement from the daily gain in muscular power.

Case II.—Convergent strabismus. R. G——, aged seven. The right eye is strabismic to the extent that by fixation of near objects with the left the inner margin of the cornea stands opposite the punctum lacrymale. There is good central fixation of the squinting eye, which shows a hypermetropic astigmatism of 3 D, and has a vision of 0.1. The left eye is slightly hypermetropic, and has normal vision. The closest possible approximation of the half-pictures does not give stereoscopic vision. The little patient received a

[5] Javal, E.: "Manuel de Strabisme." Paris: G. Masson, Éditeur.

[6] New York Eye and Ear Infirmary Reports, January, 1898.

complete correction of the refraction. For a fortnight daily instillation of atropine was made, and she was directed to exercise the strabismic eye two hours each day, always with the fellow eye closed. With a Holmes stereoscope, and a special card having an L and an F in closest apposition, the patient was soon able to fuse the two letters into an E. Now the exercises with the movable half-pictures were undertaken and a gradual separation of the figures attained in the interest of binocular vision, until at last, when they were placed each at 4.5 cm. from the middle line, the two could for a moment be superimposed. With this daily exercise the vision of the squinting eye was increased to 4. When last seen the patient could see for the most part all of the Kroll and Dahlfeld cards correctly. While it is not improbable that a tenotomy must yet be made in this case, still the stereoscopic exercise has made the final results more sure.

Case III.—Diplopia, the result of several tenotomies. Mrs. S. M. C——, an artist, aged thirty-four years. Since the age of ten she has been myopic. October 7, 1896, an examination showed O.D., M. 4 D, A.M. .50 D. O.S., M. 4.5 D; A.M. .50 D. Each eye has a vision of G. The patient has recently submitted to four successive tenotomies, and has a distressing operative diplopia, which is always present. In reading and at her work she wears O.D. — 4 D, combined with a prism of 5° (base in); O.S.—4 D, combined with a prism of 4° (base up), but asthenopic symptoms soon occur after any continuous work.

The patient was now directed every morning to use the stereoscope, adjusting the half-pictures both vertically and horizontally, so that they appeared superimposed. After a half-hour of such exercise a record was made of the position of the half-picture.

[In these notes which follow it will be remembered that the letters A, B, C, etc., indicate the vertical, and the numbers 4, 5, etc., the horizontal distance of each in centimetres from the middle line.]

The patient wore at these exercises no correcting lenses, spherical, cylindric, or prismatic.

The record was:

| | O.D. | O.S. |
|---|---|---|
| October 6th | A | B |
| | 4.5 | 4.5 |
| October 10th | C | A |
| | 6.5 | 6.5 |
| October 12th | A | B |
| | 4 | 4.5 |
| October 20th | B | B |
| | 6.5 | 5 |
| October 24th | B | B |
| | 4 | 4 |
| November 7th | B | B |
| | 4 | 4 |

This last record, which shows nearly muscular equilibrium, remained unchanged, and the patient received for reading and painting O.U. + .5 O. D.C. (180°). The diplopia was no longer present and the asthenopia had disappeared.

**Hemorrhage in the New-Born.**—When the hemorrhage is from the umbilicus, we should begin by loosening the dressings and trying different methods of ligature, but in some cases all seem to be absolutely useless. In case of gastro-intestinal hemorrhage the infant should be placed in an incubator at a temperature of 37° C., or in warm cotton. Three times daily it should have mustard baths, followed by friction with alcohol, hot baths, hot-water bags to the abdomen, hot whiskey, and subcutaneous injections of a solution of sodium chloride 7 : 100, in amounts of from 10 to 15 gm., repeated four or five times daily.—H. Brooker Mills.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 7, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 130 | 143 |
| Typhoid fever | 61 | 20 |
| Scarlet fever | 76 | 2 |
| Smallpox | 1 | 0 |
| Measles | 71 | 5 |
| Diphtheria | 151 | 23 |
| Laryngeal diphtheria (croup) | 7 | 3 |
| Cerebro-spinal meningitis | 0 | 5 |
| Chicken-pox | 4 | 0 |

**The Buffalo Fresh-Air Mission.**—The Buffalo Fresh-Air Mission has adopted some unique methods of advertising. Among others it has fitted up a street-piano to resemble a cradle. It is advertised to play fresh airs only. It has frequently taken in $20 to $25 a day, the proceeds going to Cradle Beach, a farm of forty-seven acres on Lake Erie, where five hundred children have spent the summer.—*American Public Opinion.*

**London Statistics.**—The annual report of statistics relating to London has just been published. Taking the increase of population between 1891 and 1896 as a basis, the population of London in April, 1897, would be estimated at 4,474,330, an increase of 41,312, equivalent to 0.932 per cent. in the year. With respect to births, marriages, and deaths, the statistics quoted stop at 1896 with births for that year: males, legitimate, 65,928, illegitimate, 2,552; females, legitimate, 62,862; illegitimate, 2,481; making a total of 133,833, showing a decrease of 322 over the previous year. Of the 79,744 people married in London in 1896, 35,754 were bachelors, 36,755 spinsters; 43,118 widowers, and 3,117 widows. The provision of healthy dwellings for the working classes was now recognized as one of the most important of municipal duties. Dealing with the principal zymotic diseases the medical officer of health reported that with regard to smallpox, the neglect of vaccination in London of recent years appeared to be already manifesting itself in an increase in the proportion which deaths of children from smallpox bore to deaths from this disease at all ages. The number of London children in reformatory and industrial schools at the end of 1897 was 1,208 boys and 116 girls under the London County Council, and 2,963 boys and 888 girls under the London School Board. The total number of lunatics belonging to the county of London, including imbeciles in workhouses, on January 1, 1898, was 20,482, ranging from 1.9 per 1,000 in Penge and Hampstead, to 11 per 1,000 in the Strand, while the average for the county was 4.6. The proportion of recoveries to admissions seemed to be increasing, and the proportion of hereditary causes of insanity was notably large.

**Instruction in Cookery for Medical Men.**—A well-known professor of medicine in Berlin used to say, in his clinical lectures, that a medical man ought to be at home not only in the laboratory but in the kitchen—a dictum the truth of which is occasionally apparent when practitioners in prescribing diets for patients are embarrassed by questions relative to the method of cooking. The great majority of medical men are unable to give precise instructions to a cook, while, on the other hand, many unqualified practitioners impress the public mind by their careful directions as to the prep-

aration of their patients' food. Some medical men, as, for instance, Professor Ewald, in an article in the "Handbuch der Ernährungstherapie," have referred to this fact, and have expressed a wish that medical men had opportunities of learning the rudiments of cookery. The *Berliner klinische Wochenschrift* now informs the medical profession that two ladies, superintendents of schools of cookery for girls, have arranged to give special courses for medical men. It is not said in the advertisement whether the medical pupils of these ladies will have to do practical work by grilling chops, cooking potatoes, or boiling vegetables, or whether they will only have to listen to the verbal explanations of their instructors. The offer of the ladies to open cookery classes for medical men will be heartily welcomed by those who think that medical training ought to be much more practical than has hitherto been the case.—*The Lancet.*

**The Influence of Environment and Heredity.**—The two great factors that determine our existence are heredity and environment. They also affect our moral life. Environment includes all those elements that influence us after birth, of which example and education are the most powerful. There is, then, first the criminal by heredity. There may be either a direct transmission of criminal tendencies or merely a transmission of degenerative traits, which may develop into criminality in the children, even though the parents were otherwise defective.—M. P. E. Groszmann.

**Miscegenation.**—The marriage of an educated white woman with one of the Zulus on show in London has deeply stirred the British public, and has once again brought into prominence the fact that the aversion displayed by the Anglo-Saxon race to such unions is as strong as ever it was. The *Spectator*, referring to the matter, says: "The extreme dislike of Englishmen and Americans for the half-caste races is intelligible, for it is founded on a wide though imperfect experience. That the majority of modern half-castes are inferior in several respects to both the races which produce them may be true enough—though it is often quite false—and is to be expected, for they are the progeny of illicit connections and brought up under circumstances which take the bone out of the character. But that a half-caste nation would be necessarily a base nation either in intelligence or character is by no means proved. The verdict of history is rather the other way. It is as certain as any fact of the kind can be that the Brahmins of India and the clans of Rajpootana descend from white invaders, who, crossing the passes, left their wives behind, and settling in India intermarried with the dark races of the plain. No people on earth can claim to be more intelligent than the Brahmins, and hardly any exhibits a finer character than the Rajpoot, who is moreover in physique one of the superior races of mankind. The mixture of colors cannot, therefore, be pronounced injurious to the world, though as a rule it is injurious to the individual family."

**The Influence of Self-Assurance on Conduct.**—Dr. Harry Campbell read a paper at the psychological section of the British Association, taking as his text the above title. After claiming that a belief in one's qualities, either mental or bodily, when carried to extreme lengths is a condition of disease, he writes as follows on the help that the possession of self-conceit is in the battle of life: "Self-assurance is a very useful attribute. It is helpful in every walk of life. The self-confident man steps to the front, while his brother, much more highly gifted perhaps, but lacking his self-assurance, is left behind. Who does not know of men who have achieved success through sheer cheek, and of others whose reserve and diffidence have prevented them from attaining the position to which their abilities entitled them? Doubtless the success of the self-assured man is largely the outcome of the sense of well-being and exuberant energy accompanying it. These attributes run well in harness; the energy impels a man to be up and doing, while the self-confidence gives promise of victory. How powerfully the two attributes—energy and self-assurance—make for success is well shown by what occasionally happens in the early stage of general paralysis of the insane, before the intellect is disturbed, when, indeed, its activities may be heightened in consequence of the general exaltation of nervous function."

**Meeting of Vegetarians.**—A vegetarian conference has recently been held in London, at which several American upholders of this doctrine were present. One enthusiastic propagator of the doctrine declared that although the average life of a man is but forty-eight years, he saw no reason why people who ate vegetables and fruits instead of the enormous quantities of meat now consumed should not live to an average of at least ninety-four years, while one hundred and twenty would be no uncommon age. Dr. Loretto Kress, an American woman doctor, argued that the flesh of animals tainted the blood of human beings and injuriously affected the nervous system and mind. Professor Bronson Alcott, of Concord, said that if a man ate pig he became pigified, if he ate an ox he became oxified, and so on. That was to say, that the nature of man assimilated that of the animals upon the flesh of which he subsisted.

**Care of Consumptive Sailors.**—Passed Assistant Surgeon J. O. Cobb writes in the annual report of the Marine-Hospital service for 1898 on what is to be done in the way of treatment with the consumptive sailor, and from his own experience draws the following conclusions: "The mortality of the consumptive sailor, as shown by the annual reports, is 21 4 per cent. The actual mortality, if it was possible to obtain correct data, would probably be forty per cent. The eventual mortality is probably one hundred per cent. The results obtained to-day are no better than were obtained twenty years ago if we are to rely upon statistics—*i.e.*, relative mortality, 1873 to 1877, 21.5 per cent; relative mortality now, 1890 to 1895, 23 per cent. The results obtained to-day are not better than were obtained ten years ago, *i.e.*, mortality from 1880 to 1885, 22 9 per cent.; now 23 per cent. The improvements made in our hospitals have not lowered the mortality. The present methods of treatment have not lowered the mortality, but probably have attenuated the cases. There are probably more cases now than ten years ago. Our hospitals are foci of infection, dangerous to officers, attendants, and patients suffering from other diseases. Granting the most liberal allowance for faulty conclusions from the data at hand, it is quite probably that the Government can build sanatoria for these men, transport them to these places, and take care of them to a termination of the illness, for the amount that would be expended in their care at hospitals."

**Poisoning from Artichokes.**—M. Roger has reported to the Société de Biologie a small epidemic of gastro-enteritis which occurred in his practice recently, which he was able to trace directly to the ingestion by those attacked of preserved or canned artichokes. Examining the contents of one of the boxes the vegetable was found to be of a handsome, almost natural green color, which at first gave him the idea that he had to deal with the effects of a copper-salt chemical. Analysis, however, revealed not a trace of that metal. He then submitted the material to an examination by bacteriological methods, and was able to isolate a coli

bacillus and a micrococcus. The latter on cultivation was found to have the property, when cultivated on slices of artichoke, of communicating to the latter an intense green color. The micrococcus is pathogenic to the rabbit.—*The Sanitarian.*

**Sir James Paget,** says an English weekly, now lives a very quiet life at Park Square West, almost his sole companion in his declining years being his daughter, who is devoted to him. Besides being famous as a skilful surgeon, he is well known as an orator, and his gift of eloquence has descended to his two sons, the dean of Christ Church and the vicar of St. Pancras. Sir James never sought publicity, and all the recognition bestowed upon him has been fully earned, for in all his labors can be discerned that freedom from assumption which is characteristic of the true physician. It would be difficult to estimate how many medical men of the present day in England owe their success in life to the words of counsel and advice given them by Sir James Paget years ago, but it must be a large number. He was the students' friend.

**The Metric System in Great Britain.**—The associated Chambers of Commerce of Great Britain at their meeting on the 6th inst. adopted almost unanimously the following resolution: "That the association, reaffirming its frequently expressed opinion that the metric system of weights and measures should be made compulsory in the United Kingdom, strongly urges her majesty's Government to use it in all government departments and to enforce strictly the existing provisions in the education code with regard to the teaching of examination in the subject in elementary schools, and that representations to this effect be made to the Government."—*Medical Press.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 7, 1899:

| | | Cases. | Deaths. |

**Fungous Foot.**—An instance of Madura foot has been reported by Drs. Arwine, of Texas, and Lamb, of Washington, in the October number of the *American Journal of the Medical Sciences*, making the fifth case recorded in this country. The patient was born in Texas, of Mexican parents. The first evidences of mycetoma were noted in 1887, when a severe pain in the foot, lasting thirty-six hours, was followed by a red spot, and subsequently an enlargement which was considered elephantiasis. Amputation was performed in 1889 and the specimen was sent to the army medical museum. It is thought probable by the writers that the specimens of many erroneously diagnosticated instances may be hidden away in museums. The only other specimen in the army museum came from Texas.

## Books Received.

### THE EARLY DIAGNOSIS OF CANCER OF THE STOMACH.

BY JOHN C. HEMMETER, M.D., PH.D., ETC.,

PROFESSOR IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF MARYLAND, AND DIRECTOR OF THE CLINICAL LABORATORY, BALTIMORE.

A NUMBER of important articles from the pens of eminent authors recently published upon this subject do not really deal with the *early* diagnosis of cancer of the stomach at all. Thus the determination of the size of the stomach, the efforts to detect the presence of tumor, the symptoms of pain and hemorrhage, the deglutition sounds, the various conditions of the histological elements of the blood, the evidences found in the gastric and urinary chemical and microscopical analysis, the state of bodily nutrition, though very important when taken in conjunction—do not offer, as our further discourse shall show, anything absolutely reliable or pathognostic for the early diagnosis of cancer of the stomach. Czerny, Rindfleisch, and Kraske have emphatically stated that gastric cancer should not be radically operated upon after it can once be diagnosed as a tumor. All the clinician can do in these cases is to perfect the methods for early diagnosis so as to enable the surgeon to perform an operation when the histological changes of the neoplasm are confined and restricted. I do not consider that our present knowledge and diagnostic methods of detecting this dreadful disease are at all complete. In fact, certain histological examinations which I have made in my own laboratory, to be published in the near future, convince me that an entirely new and hitherto scarcely used method of diagnostic technique may perhaps be able to afford us valuable aid in the direction pointed out. Lindner and Kuttner have asserted that the early diagnosis of cancer of the stomach is impossible, and Haberkant goes even a step further and insinuates that it will never be possible to diagnose cancer of the stomach at a stage when it can be radically operated upon. I will let one of the most versatile of American surgical philosophers reply to this objection, inasmuch as the quotation exactly echoes my sentiments in this matter: "Till then one lesson for all of us is that the hope of the patient lies in early and thorough operation. At present, instead of doing pylorectomy for cancer, owing to adhesions, metastasis, the extent of the tumor, or the wretched condition of the patient, we are obliged to content ourselves with the makeshift of gastro-enterostomy. If we explore early, we can select a time when the patient is in good health, and then we can not only make a thorough operation by removal of the disease itself, but can remove all enlarged glands which would imperil the patient's future. I believe the time will come when carcinoma of the stomach will fall in line with carcinoma of the breast, of the rectum, of the uterus, and early and complete operation will add new laurels to the crown of surgery by many permanent cures. I believe that ulcers will be submitted to early excision and not be permitted to destroy life by perforation or hemorrhage.

"In order to bring about this happy day, the surgeon must have the hearty co-operation of the physician. It is sometimes said that surgery has made more progress of late than medicine. I do not believe it. The triumphs of surgery, it is true, are more dramatic, but in the diagnosis and treatment of diseases of the stomach the physician is quite abrest with his brother the surgeon. When all physicians appreciate what the surgeon can do if he be called in promptly, then shall we see results that will be as gratifying as they are startling."[1]

Let us begin with a brief consideration of the statistics of cancer, showing an alarming increase of this disease—the world over—during the end of the nineteenth century.

According to the reports of the registrar-general, the mortality from cancer in England and Wales is progressively increasing out of all proportion to the increase of the population, and with a rapidity that may well arrest the attention of sanitarians. A study of a table compiled from these reports, and published by Mr. W. Roger Williams in *The Lancet* of August 20, 1898, shows us that in 1840 cancer caused 2,786 deaths, the proportion being one in 5,646 of the total population and 1 in 129 of the total mortality, or 177 per million living; in 1896 the deaths due to it numbered 23,521, or 1 in 1,306 of the total population and 1 in 22 of the total mortality, or 764 per million living. Thus the proportionate mortality from cancer now is four and a half times greater than it was half a century ago.

It is impossible to explain this remarkable increase in the mortality from cancer otherwise than by an increase in the prevalence of the disease. The assumption that the increase is only apparent and is due to improved methods of diagnosis is untenable, for it is probable that the reverse is nearer the truth and that many cases formerly diagnosed as cancer are now classed under other heads. The attempt to explain this increasing mortality as due to the average age of the population having advanced, and the consequent greater liability to cancer, will also not bear critical examination, Mr. Williams shows, for the saving of life in modern times has been mainly confined to early years. The number of deaths among men over thirty-five years and women over forty-five years has remained stationary or increased, while the number of persons who attain old age has decreased.

In respect of this immense increase in mortality cancer is unique, for nothing at all approaching it is furnished by the statistics of any other disease, and yet no effect appears to have been produced on the medical profession or the general public by these startling figures of the registrar-general's reports. Concerted efforts are being made to stay the progress of tuberculosis, while the warning of the cancer mortality is neglected. Yet, if the disproportionate increase in deaths from malignant disease continues, cancer will soon be as lethal as typhoid fever, smallpox, and tuberculosis combined. In the face of these

[1] W. W. Keen, LL.D., etc.: Philadelphia Medical Journal, vol. i., page 1105.

statistics it behooves sanitarians to investigate with great care the conditions which favor the development of cancer, whether these be personal or regional, dietetic or microbic, for it is only by the avoidance of the main etiological factors that a decrease in the prevalence of cancer can be attained.[1]

The increase of mortality from carcinoma in England has been from one in seventy-four in 1854, to one in twenty-three in 1894. A small proportion of this increase has been ascribed to the greater number of survivals to the higher ages. For the remainder two explanations have been advanced: either there has been a real increase in the mortality from carcinoma (in proportion to the number living at each group of ages), or the great increase is caused by improved diagnosis and more accurate certification of death on the part of medical practitioners.[2]

In 1840, in England, the proportion of deaths from cancer to the total mortality rate was one in one hundred and twenty-nine; in 1880 this had risen to one in twenty-eight, which shows that in England the death rate from cancer is now about four times greater than fifty years ago. Williams estimates that at least forty thousand persons are now suffering from cancer in England and Wales, whereas in 1840 the number was only about fifty-five hundred. Should the disease increase in the future at the same relative rate, it will become one of the commonest of all. This augmented mortality corresponds with increase of population in wealth and improvement in general sanitary conditions. In Ireland, where this happy condition of affairs does not obtain to a corresponding extent, the cancer death rate has been much smaller and has shown no such marked increase. In 1861, in England, there were three hundred and seventy-six deaths from cancer to the million of population; twenty-five years later there were six hundred and ten. During this quarter of a century the number of deaths from phthisis per million has diminished to three-fifths of the number at its commencement.

In the twenty years from 1870 to 1890 the increase in mortality from cancer in England is as follows: In 1870, 384 to the million; in 1880, 468; in 1890, 590. Accepting these published figures from the registrar-general's report, it would appear that the mortality has increased by fifty-three per cent.

From a tabulation of the deaths within the State of New York during ten years, from 1885 to 1895, I find that during this time there have been reported 30,692 deaths from cancer. Doubtless in a few of these cases there may have been a mistake in diagnosis, which will, however, be abundantly atoned for, and more, by the deaths which were really due to cancer and ascribed to some other cause. In 1885 there were 1,882 deaths from this cause; in 1890, 2,878; and in 1895, 3,454. In other words, in the last year of this decade the total number of deaths from cancer was twice that of its first year—which may be interpreted as meaning that the death rate has increased much more rapidly than has the population. During this same decade, also, the number of deaths from all causes has increased only from 80,000 to 121 000. During the last five years of this decade epidemic influenza alone caused 35 000 of the 121,000 deaths. It will therefore be seen how rapidly the cancer death rate is creeping up.

In 1892 Haviland published a monograph, in London, on the "Geographical Description of Heart Disease, Cancer, and Phthisis in England and Wales," in which he maintained that where cancer is most prevalent the country is low and traversed by rivers, which frequently flood the adjoining country; whereas cancer is relatively scarce in mountainous regions or where floods do not occur, and where the subsoil is either hard or absorbent. Thus he found that the Thames runs through a vast cancer field, excepting only where the chalk crops out. Williams, however, states that this cannot be true of all low-lying countries, and seeks to explain the prevalence of the disease in the valley of the Thames by conditions of life peculiar to its population. He calls attention to the fact that cancer mortality is lowest where the struggle for existence is hardest, the population densest, the general mortality highest, the average duration of life shortest, where sanitation is least perfect, and the death rate from tuberculosis highest—in other words, among the working classes—whereas the cancer mortality is greatest among the agricultural community, where people are well-to-do, and where the standard of health is highest and of life easiest. He believes the most potent factors in the causation of cancer to be high feeding and easy living, and that the farmer is in general better off than the city laborer, but more liable to cancer. So, too, in London, where the cancer rate is highest, it is significant that this is particularly true of those parts where the wealthy most abound.[1]

In 1889 England lost 18,654 of her people from cancer, this number being 3.6 per cent. of the entire death rate for that year. In 1893 London alone lost 3,412 of her population from this cause, a percentage of 3.73 of the total death rate for the year. And during the ten years preceding 1895, the death rate from cancer increased 0.87 per cent.

In Berlin in 1892 "cancer and tumors" destroyed 1,138 of the population, a rate of 3.48 per cent. of the total deaths for that year. In the same city in 1877 the deaths from these causes are recorded at 2.10 per cent., showing an apparent increase of 1.38 per cent. in fifteen years.

In Vienna the deaths from cancer in 1890 were 4.96 per cent. of the total death rate for that time, and during the preceding eight years the death rate from the same cause had increased 0.84 per cent.

In Paris, in 1893, cancer caused 4.61 per cent. of the total death rate.

The average death rate from cancer in New York City during the ten years prior to 1895 was 2.17 per cent. of the total mortality of that period, showing an increase of 0.35 per cent. in the preceding ten years.

Permit me to add, in brief, in connection with other important cities in the United States, that in 1895 Philadelphia showed an increasing rate of 0.26 per cent.; Boston 0.54 per cent.; Baltimore 0.64 per cent. In Baltimore the loss by death from cancer is 3.52 per cent. of the entire death rate; New Orleans 0.52 per cent.; and San Francisco, 0.84 per cent. during the preceding ten years.

It may not be uninteresting to note the fact that the deaths from cancer in fifty of the large cities of the United States is 16.34 per cent. greater per 100,000 living than in the remaining portion of the country. It is proper to say, however, that a part of this difference can be justly attributed to the comparatively greater completeness of the mortality records of city districts, and to the presence in the city of those who seek the advantages it offers for relief.

**Frequency of Carcinomatous Invasion of the Stomach.**—At all events, it now appears that those parts of the body possessed of especial physiological significance, and which are exposed to the evil effects of perverted appetite and mischievous habits, are foremost

[1] "Statistics showing the Increase of Cancer, particularly of Cancer of the Stomach." MEDICAL RECORD, September 24, 1898.

[2] Arthur Newholme: "An Explanation of the Supposed Increase of Cancer Mortality in England." British Medical Journal, January 8, 1898.

[1] Roswell Park: "Prevalence of Cancer and Its Increase." MEDICAL RECORD, July 3, 1897.

in the field of malignant development. In 1,000 deaths from cancer in New York City in 1893, the tongue was the seat of disease in 18, the œsophagus in 19, the stomach in 253, the intestines in 39, the rectum in 42, the uterus in 196, and the breast in 91 instances.[1]

According to the statistics of Haberlin of 27,511 cases of death from cancers, 11,422 of the cases of cancer occurred in the stomach; that is 41.5 per cent. This number agrees with the statements gives by d'Espine, according to whose calculation 44.3 per cent. of all cases of carcinoma occuurred in the stomach. According to Brinton, one per cent., and according to Wyss two per cent. of all deaths are attributable to cancer of the stomach. The physician is helpless in the treatment of this disease. Everything that can be done to postpone or perhaps prevent the inevitable fatal termination lies in the hand of the surgeon. It is an imperative demand to be laid upon the practitioner that he should consider the possibilities of an operation from the very beginning of the presentation of cancer of the stomach, and as the only operation which can promise relief for a longer time is an early operation—*i.e.*, the earlier an operation is undertaken the more favorable are the prospects of a prolonged period of life after the operation—the deduction is evident that an early operation depends upon an early recognition of the disease. If we disregard the very rare cases in which gastric cancer remains latent, or runs its course under very obscure symptoms, not at all referable to the stomach, we may distinguish two groups of cases: (1) those in which the local symptoms predominate, and (2) those in which the general symptoms predominate.

**Age.**—According to the tables of Brinton 600 cases, Welch 2,075 cases, and Haberlin 11,424 cases, three-fourths of all cases of gastric cancer occur between the ages of forty and seventy. The factor of age should, however, be used only with the greatest of caution. Of 66 cases of Lindner and Kuttner, more than one-half of the patients had not reached the fiftieth year. The same can be said of Hammerschlag's cases. I have repeatedly had the experience that general practitioners have failed to recognize cancer of the stomach on account of the youthful age of the patient. Now Wilkinson has reported a case of congenital gastric cancer, Cullingworth one in a child five weeks old, and Widerhofen a congenital cancer; Kaulich a colloid carcinoma in a boy one and a half years old. According to Schaffer the percentage of gastric cancers in the first three decades is two per cent., according to Reichert three per cent., and according to Bräutigam 2.5 per cent.[2] One fact I should like to emphasize in connection with the question of age, and that is that the limit of age for carcinoma is gradually receding.

**Diagnostic Value of the Subjective and Objective Symptoms.**—Among all the dyspeptic complaints, the disturbances of appetite, thirst, the pressure, distention, and fulness, the eructation, nausea, and vomiting, and the irregularities of the stool, there is nothing characteristic. Thirst is particularly prominent and a very annoying symptom in dilatations caused by pyloric carcinoma. There is nothing characteristic about the pasty, insipid taste nor about the coated tongue. The pains are not characteristic. The vomiting and nausea when very frequent and copious are suggestive of cancer at the pylorus or at the cardia. When the two openings of the stomach are free, and only the walls of the stomach are affected, there is in my experience no vomiting at all. The amount that is vomited depends upon the degree of dilatation. The food is unchanged. In my experience, blood is contained in the vomit in one-half of all cases of gastric cancer. Large quantities of blood are rarely vomited, but the characteristic coffee-ground vomit, in consequence of stagnation and decomposition of the blood, is diagnostically important. The more copious the effusion of blood is into the stomach, the quicker does it cause vomiting; for that reason the abundant hemorrhages in ulcer are often vomited uncoagulated and very little altered, whereas the smaller amounts of blood in carcinoma and gastritis remain in the stomach a longer time and then show the characteristic coffee-ground appearance. But large hemorrhages may occur in cancer, and small hemorrhages may occur in ulcer; and I have seen cases of coffee-ground vomiting in ulcer repeatedly.

**Constipation or Diarrhœa.**—In the literature of the subject, in which any reference to these points was made, I found that in seventy-five per cent. of cancers of the stomach there is constipation. In about twenty per cent. there is diarrhœa, and in five per cent. only does the stool remain regular. These figures agree with those from my clinic sufficiently to make any alteration needless. F. Muller states that diarrhœa occurs in 35.5 per cent. The greater frequency of constipation is due to the mechanical stenosis by the tumor, and motor insufficiency due to carcinomatous invasion of the muscularis.

**Emaciation and Cachexia.**—That these symptoms are not characteristic is evident, but they are important because the degree of emaciation will greatly influence the decision on an operation. A frequent question will be, Will the strength of this patient suffice to overcome a severe abdominal operation? The general condition gives no clew to the size of the tumor. A very minute cancer, even when it is at a place where it in no way influences the functions of the body, may depress the nutrition of the entire organism, and irresistibly lead to death. On the other hand, very large tumors on the walls of the stomach may run a long course without disturbance of the general strength and nutrition.

So in all dyspeptic symptoms there is nothing pathognostic for gastric cancer. They occur not only in other diseases of the stomach, but to a large extent in the diseases of other organs. The swelling of the cervical lymph glands is a very rare sign, and in my experience occurs only toward the end of the disease, by which time the diagnosis is generally clear.

**Condition of the Gastric Functions.**—The secretion: During the development of cancer, secretion of hydrochloric acid is gradually lost, so that free HCl can no longer be detected in the test meals. Toward the end stage, both free and combined HCl are entirely absent. It is urgently necessary to be very careful in these determinations for HCl. A single analysis, showing sub- or an-acidity, proves nothing at all. If a first test fails to detect free HCl, it should be repeated after allowing a longer interval to elapse subsequent to the time at which the test meal was taken. It must be borne in mind that the gastric mucosa does not secrete HCl all over, *i.e.*, in all of its parts. Only the middle portion secretes HCl; the pyloric region does not secrete it. Although the degree of reduction of HCl secretion depends upon the extent and the gravity of the gastritis which is caused by the carcinoma, nevertheless this may be limited to the pyloric region, where it will not interfere with the glandular apparatus which forms the HCl. F. Mall[1] concludes with Heidenhain that the oxyntic or border cells in the peptic ducts are concerned in the production of HCl, and the central cells in the production of pepsin. Now as the pyloric region contains no border cells, a carcinoma may reach as far as the antrum pylori, a

[1] Dr. Joseph D. Bryant, in the MEDICAL RECORD, December 3, 1898.

[2] See Inaugural Dissertation von Reinhold Schulz, Breslau, 1886.

[1] Johns Hopkins Hospital Reports, vol. i.

distance of three to five inches, before it will invade the region which contains the acid or border cells. I have seen six cases in which the presence of free HCl continued to the end of life. In two of these cases the carcinoma was seen during the operation, and in the remaining four at autopsy. These six cases had not originated on the basis of an old gastric ulcer, but were circumscribed knots of cancer, leaving the mucosa intact. In all cancers that have arisen from ulcers, free HCl in normal or even in increased amounts may continue until death. This is sufficient evidence for the conclusion that the presence of free HCl does not argue against cancer of the stomach. On the other hand, absence of free HCl is no specific sign of this disease. It occurs in other gastric diseases leading to atrophy; it may occur in diseases of other organs, for instance diseases of the kidneys, pulmonary tuberculosis, and valvular cardiac diseases, and, as I have shown,[1] free HCl is frequently absent, though not necessarily so in catarrhal jaundice. When free HCl is absent, combined HCl may still be present, and Schüle argued that the amount of the HCl deficit was an important diagnostic sign between cancerous and benign diseases of the stomach.

In determining the amount of the HCl deficit, decinormal HCl solution is added to the filtrate of gastric contents until we get a distinct reaction with the Boas resorcin test or any of the other established tests for free HCl. The degree of the deficit is in my experience no indication of the extent of atrophy of the secreting apparatus. Very large HCl deficits have been discovered by myself in benign diseases of the stomach. The determinations for HCl, however, when taken in conjunction with other symptoms and signs, have a certain limited diagnostic significance.

Secretion of pepsin and chymosin or rennin: As a rule, the reduction of the secretion of these ferments goes parallel with a reduction of the HCl secretion. For clinical purposes, the determination of the presence and strength of the pepsin secretion may be made according to the method of Hammerschlag,[2] though this method from a chemical standpoint is by no means exact Hammerschlag uses the Essbach albuminometer to determine the amount of albumen which has not been digested by the pepsin of the gastric contents. As this method is not exact when used for urinary analysis, it is less so for this purpose. Still, as a rough clinical test it generally suffices.

Method: A one-per-cent. solution of albumen containing free HCl to the amount of 4 per 1000 is filled into the Essbach albuminometer to the 10 c.c. mark. To this tube we add 5 c.c. of the gastric filtrate to be tested for pepsin. A second Essbach albuminometer is filled to the 10 c.c. mark with the standard egg albumen and HCl solution, and as a control test 5 c.c. of distilled water is added. Both tubes are now put in the incubator at a temperature of 37° for one hour. Then the amount of albumen is determined in each by the Essbach reagent. After both tubes have been allowed to stand quietly for twenty-four hours the amount of digested albumen can easily be calculated in numbers expressing the percentage. This test is not sufficiently delicate to demonstrate small amounts of pepsinogen.

The reduction of the chymosin or rennin occurs without exception in gastric carcinoma, but very marked reduction in the amounts of both ferments is in itself not a characteristic sign for gastric cancer, because it can occur in atrophy of the mucosa from gastritis, and also from long-standing diseases of other organs.

Lactic Acid: In one hundred and twelve cases of carcinoma of the stomach, I found only three in which lactic acid was present to any considerable degree before the diagnosis could be made by other symptoms. The frequent occurrence of lactic acid in gastric cancer has been asserted by Boas to be an important diagnostic sign. The question is, Does it occur at a time to enable us to make an early diagnosis? This I must deny on the basis of a large experience with this test. Boas has admitted that excessive lactic acid in the stomach contents is not a pathognostic sign of cancer of the stomach, because it is absent in a number of cases of that disease, and may be present in gastric diseases of a benign type, and even during diseases of other organs.

Three conditions are necessary, possibly four, to bring about excessive formation of lactic acid in the stomach. These are: (1) impaired gastric motility; (2) absence of HCl secretion; (3) reduction of albumen digestion; and (I should add) (4) an impaired absorption. Lactic acid is formed in the stomach by the action of lactic-acid bacilli on the carbohydrates. Sticker has shown that the simple passage of carbohydrates through the mouth causes the formation of more or less lactic acid without exception. It is therefore necessary to give a test meal, which shall be, so far as practicable, free from lactic acid, and which shall form little of this substance during the passage through the mouth. Such a test meal has been introduced by Boas in the form of his oat-flour soup (one ounce of Knorr's oat flour boiled in a quart of water, evaporated down to one pint, and seasoned with salt only).

Lactic acid will not form in the stomach even though the contents stagnate due to arrest of the peristalsis, and although the HCl secretion is reduced or absent; provided the proteid digestion is still fairly good, and does not fall below seventy-five per cent. Whenever there is much lactic acid in the stomach, the proteid digestion will be found to be below seventy-five per cent. I have made a number of chemical tests, relative to the relation of lactic acid to proteolysis, and confirmed the view that lactic acid may replace the normal HCl. In the contents of some carcinomatous stomachs the lactic acid was found to be in combination with the proteid of the food. When the mucosa is still capable of secreting HCl, this will combine with the albumin sooner than the weaker acid; hence a fairly good albumin digestion signifies still a trace of HCl and ferments. But a fairly good albumin digestion can be effected by lactic acid and pepsin in the absence of HCl. This chemical factor merits closer investigation. Normally lactic acid, like all other soluble products of digestion, is absorbable. If, therefore, the absorption is made difficult, which occurs especially when the contents stagnate and the HCl secretion is depressed, the conditions favorable to lactic-acid accumulation will be present. Whenever the movements of the stomach are normal, so that the contents can be expressed into the duodenum within six or seven hours, lactic acid will not develop to a degree that can be recognized by the ordinary tests, although the HCl secretion has been lost entirely. Hammerschlag took such gastric chyme containing no HCl, but from stomachs with normal motility, and added the third necesary factor (viz., stagnation), by letting it stand at room temperature. Under such stagnation lactic acid rapidly developed in the chyme. In gastric carcinoma we have the conditions favorable to lactic-acid formation in the majority of cases: suppression of HCl, stagnation of contents, impaired proteid digestion, and impaired absorption, so that lactic acid is found most frequent in cancer of the stomach. Rosenheim found it in seventy-eight per cent., Lindner and Kuttner found it in sixty per cent., Strauss found it in ninety-one per cent., and I have

[1] Hemmeter: "Diseases of the Stomach," second edition, p. 374

[2] Archiv f. Verdauungskrankh., vol. ii., p. 4.

found it in eighty-two per cent. of all of my cases of gastric cancer. But the conditions necessary to its formation in the stomach can be brought about by diseases other than cancer; for instance, in benign pyloric stenosis, in atrophic gastritis with motor insufficiency, and even in diseases of other organs I have discovered lactic acid in the stomach in marked excess when the stomach itself was not affected, but the impaired peristalsis was caused in one case by a pancreatic cyst, in another case by a carcinoma of the gall bladder, and in a third case by a large gall stone. These conditions had caused compression of the duodenum effecting obstruction to the outlet of gastric chyme with a subsequent gastritis, the latter most probably causing the loss of HCl secretions. In still another case in which there was compression of the duodenum by floating kidney, the presence of lactic acid was only transient. Whenever the kidney could be retained in place by a proper bandage, the stomach resumed its secretions partially, and the peristalsis was to a degree resumed, and the lactic acid, except in minute traces, disappeared from the contents. Lactic acid, then, although it is not an early sign, is a clinically important sign. It means absence of HCl, stagnation, and reduction of the digestive ferments and absorption; conditions which are most frequently found in cancer, and therefore the presence of lactic acid, although not a pathognomonic sign, nevertheless when it occurs in conjunction with other symptoms should suggest the probability of cancer. The test necessary for this which is most practical is the one originally suggested by Uffelmann. The reagent consists of 10 c.c. of a four-per-cent. solution of carbolic acid, 20 c.c. of distilled water, and one drop of the liquor of the sesquichloride of iron. This gives an amethyst-blue solution. The presence of lactic acid changes this to a yellowish green. The reagent is sensitive to 0.5 per 1,000 of lactic acid, which amount is always pathological and of diagnostic significance. Tests more sensitive than this would not be useful clinically. Boas[1] has given an exact method for quantitative determination. Straus[2] has devised a practical little funnel for separation of the lactic acid by agitation with ether (for illustration, see Hemmeter's "Diseases of the Stomach," page 160).

**Microscopical Examination of the Stomach Contents.**—There are only two structural elements in the stomach contents that have a possible diagnostic significance. These are: (1) tissue fragments, minute portions of the neoplasm; (2) the so-called Oppler-Boas bacilli. The tissue fragments are of undoubted diagnostic value if they contain structure of the neoplasm. The question is, Do they occur early enough in the disease to make a timely diagnosis possible? It is probable that the fragments are only detached from ulcerating tumor masses in the stomach, such as have already developed metastases, but I shall describe a method, that of curetting the walls of the stomach with a soft tube, and thereby loosening the superficial epithelium at a time when the neoplasm is not yet ulcerating. These fragments can be washed out of the stomach by lavage and sedimented in the electric centrifuge. I have used this method in forty-eight cases of gastric carcinoma, and I regard it as eminently important and adapted to early clinical diagnosis. I wish to emphasize that not only fragments of the neoplasm itself are to be sought after, but any cellular tissue that is found should be carefully stained and studied. The most remarkable feature of the sediment from such a stomach, after this so-called curetting, is a large number of cells presenting karyokinetic figures. Rieder[3] reported a case in which he made a diagnosis of malignant disease of the peritoneum and pleura from finding numerous cells in the exudates, showing indirect nuclear division. Mitoses occur very frequently. The forms of cell and nuclear division known as the equatorial plate and the monaster are frequent. Another form known as the anaphase, which in normal karyokinesis precedes the formation of the daughter stars and leads up to the formation of the resting daughter nuclei, has been observed three times in the curettage from stomachs at a stage when there was no tumor palpable, and in which the diagnosis was confirmed by operation, autopsy, or by the later development of a tumor. The presence of a large number of cells in the stomach after curetting with the stomach tube, which cells show mitosis, is very significant, and should stimulate further and careful examination. Sooner or later a fragment will be obtained which will give the typical structure of carcinoma. For this kind of curetting a soft stomach tube suffices, provided it has a lower and a lateral aperture, the edges of which scrape away the tiny elevations of gastric mucosa, when the tube is moved in and out of the mouth. The procedure should be carried out in the morning before breakfast, when the stomach is empty. This method of obtaining specimens from the gastric mucosa during life is free from danger, and not once in my experience has any pain, distress, or hemorrhage been produced thereby. In many cases of chronic gastritis, achylia gastrica, and carcinoma, tissue fragments are found in the lavage water without especially making an effort to loosen them, by moving the tube along the gastric walls.

The forcible detachment of larger pieces of gastric mucosa is an accident occurring during lavage by suction or aspiration of the tube, particularly when the instrument is in inexperienced hands. It is followed by copious hemorrhage, yet pain is rarely complained of. I reported a case of one of my students[1] who aspirated a piece of his own gastric mucosa 10 by 4 mm.; it was followed by a profuse hemorrhage but no other serious consequences, as uninterrupted recovery occurred under rest and liquid diet.

The Oppler-Boas bacilli are very long, rod-shaped organisms, non-motile, and usually thicker at one end than at the other, presenting the shape of a baseball bat. Kaufmann and Schlesinger[2] have isolated these organisms and asserted them to be of great significance in cancer of the stomach. Riegel[3] confirms the occurrence of these bacilli in enormous numbers in carcinoma, and adds that, although there are numerous fungi that have the property of forming lactic acid in stomach contents, this cannot alter the significance of the Kaufmann and Schlesinger observation. He does not consider these organisms as pathognomonic of gastric cancer, but as very important for the diagnosis. Dr. Harvey Adler and myself have examined fifty-two cases for the Oppler-Boas bacilli, and failed to observe them in only three cases. The presence of this organism is therefore an important factor, aiding in the diagnosis.

The test of the peristalsis or motility of the stomach should never be omitted from the diagnosis. In the majority of cases the peristalsis suffers greatly, but in cancers located at the fundus and at the curvatures, the motor power of the stomach may remain normal throughout the course of the disease. There are even rare cases of pyloric cancers in which the motor power may remain intact for a long time.

Absorption: The tests for the absorptive power of the stomach usually give evidence of great reduction in this function. There are, however, many exceptions to this rule, no doubt due to the fact that the gastric

[1] Deutsch. med. Wochenschr., 1893, No. 39.

[1] Hemmeter: "Diseases of the Stomach," p. 136.
[2] Wien. klin. Rundschau, 1895, No. 15.
[3] "Erkrankungen des Magens."

mucosa is in a fairly normal condition, notwithstanding the presence of a very circumscribed carcinoma.

Urine: Investigation made hitherto on metabolism and the constituents of the urine have in my opinion not as yet yielded any results of practical value for the diagnosis. Albumin is present in from thirty-five to fifty per cent. of the cases according to F. Müller. Excess of indican is present in from eighty-five to ninety per cent. of the cases.

Blood examinations: These have shown a reduction in the percentage of hæmoglobin and absence of the digestive leucocytosis. Frederick P. Henry has emphasized the fact that in gastric carcinoma the red corpuscles number two to three millions per cubic millimetre, whereas in pernicious anæmia, which most resembles cancer of the stomach, the count is much lower, sometimes less than 500,000.[1] This phenomenon will serve to distinguish these two diseases.

Tumor: Demonstration of a tumor in the stomach is the most reliable evidence upon which to base a diagnosis, but it is not an early diagnostic sign. According to various prominent German surgeons, the presence of a tumor is a contraindication to the execution of a radical operation having in view the total extirpation of the neoplasm. Czerny and Rindfleisch[2] and Kraske[3] argue that gastric cancer should not be radically operated upon after it can once be diagnosed in the form of tumor. It will not be necessary for me, in this short article, to consider the methods of palpation and the mobility of gastric tumor, but I should like to recommend urgently the palpation of the patient, either in a warm bath or under anæsthesia, when a tumor cannot be made out by palpation under ordinary conditions.

**Hypertrophic Stenosis of the Pylorus—Stenosing Gastritis.**—The differential diagnosis between this condition and carcinoma is difficult. W. S. Thayer and Rosenheim have reported cases of benign stenosis that could not be distinguished from carcinoma. A history of very long-standing dyspeptic disease, with alternating improvements and aggravations, speaks for hypertrophic stenosis if the symptoms and anamnesis of chronic gastritis accompanied the development of stenosis. The presence or absence of tumor is of no diagnostic value in differentiating these two conditions. A tumor when present may as well be a benign hypertrophy as a cancer. Repeated and consecutive weighing of the patient is urgently indicated in benign hypertrophic stenosis; there will be more frequent and more lasting improvements, extending sometimes through years. Motor function and stagnation grow progressively worse in carcinoma; in benign stenosis they are amenable to treatment by lavage and diet.

In stenosis due to cicatrix from gastric ulcer there will have been a history of blood in the vomit or stool and presence of excess of HCl in the gastric chyme; if the stenosis is due to hypertrophic gastritis, these signs will not be observed, though normal amount of HCl may exceptionally be met with in the early stages of the latter.

Among all the early signs and symptoms of gastric carcinoma, the dyspeptic symptoms and the evidences of disturbed functions, and the general condition, there is not one fact that is pathognostic for an early diagnosis. I do not assert, however, like Haberkant and Lindner and Kuttner, that in the present state of our knowledge the early diagnosis of gastric carcinoma is entirely impossible.

**Diseases of the Stomach Associated with the Absence of HCl.**—A brief consideration of these will be indispensable in our efforts to reduce the possible sources of error in making a diagnosis. The atrophies that may be associated with the absence of HCl are the following: 1. Apparently idiopathic (Nothnagel and Fenwick). 2. End stages of long-standing chronic gastritis. 3. Gastric atrophies occurring with mammary, uterine, and intestinal carcinoma. 4. With benign pyloric stenosis. 5. With gastric cancer. Achylia gastrica, which has been first described by Einhorn in 1888, means the complete absence of the secretion of gastric juice, not simply of the HCl only, but also of the ferments. So-called anacidity, or achlorhydria, means the absence or loss of HCl, but pepsinogen and rennin zymogen are secreted. Achylia gastrica may be congenital. The existence of so many conditions connected with the absence of HCl secretion is an evidence of the difficulty of utilizing this sign for diagnosis. In Groups 1 and 2, however, the motility is normal; there is as a rule no lactic-acid formation, and the course of the disease is generally a long one. The atrophies described by Fenwick under Group 3 have not been as yet carefully studied as regard to their motility and the presence or absence of lactic acid. Group 4, the benign forms of pyloric stenosis, are very rare, but they can be distinguished by their long, slow course. If, therefore, the history extends over several years, no importance can be attached to the presence of lactic acid. Achylia gastrica is also a disease of long duration; the motility is always excellent, the appearance of the patient is good, and the condition of the chemistry of the stomach is always the same, showing no lactic acid, no ferments, and no HCl.

**Neuroses of the Stomach Associated with Permanent or Temporary Loss of HCl Secretions.**—These conditions are very often perplexing, and might be confused with the diagnosis of cancer, but the presence of hysteria or neurasthenia and the long duration of the disease, together with the result of curetting of the stomach for fragments of mucosa, should make the differentiation possible. Patient observation will eventually detect a period in the course of neuroses when HCl is again secreted normally.

**Gastroscopic Examination.**—Whether the gastroscope will enable us to make an early diagnosis of gastric carcinoma is a very remote problem. Gastroscopy has no doubt made distinct advances during the last ten years, but it is connected with so many difficulties and dangers that the general application of this method cannot be hoped for at present. Mikulicz, Kelling, Rosenheim, Revidzoff, and Kuttner have published their studies on gastroscopic examination of the stomach. After a critical study of their reports one cannot fail to be conscious of discouragement at the absence of practical results. There is still very little promise in this method.

**Electrodiaphany** or **transillumination** of the stomach, according to the method first suggested by Einhorn, may give a suggestion of the existence of a tumor of the anterior gastric wall. But a chance of such a demonstration will be very small. Out of thirteen hundred cases of cancer of the stomach collected by W. H. Welch[1] only thirty occurred on the anterior wall, *i.e.*, 2.3 per cent. In order to cut off the rays of the intragastric lamp a tumor must have a thickness of 1.5–2 cm.[2] These observations have been confirmed by the writer. With a tumor of such dimensions as a requisite, and the extreme rarity of the location of tumors on the anterior gastric wall, I am disposed to consider this method unavailable for the early diagnosis.

**The Use of the X-Ray for Diagnosis.**—The author was among the first to publish studies of the position and size of the stomach for diagnostic pur-

poses.[1] Boas and Levy-Dorn[2] have proposed a method of recognizing strictures of the gastro-intestinal canal by skiagraphy. Capsules coated with an insoluble material and filled with bismuth subnitrate cut off the *x*-rays, and their location can be recognized in the intestines, but I doubt very much whether this method will exactly locate a carcinomatous constriction, because the intestine is not a simple tube, but a labyrinth of convolutions, superimposed upon each other, so that even if the bismuth capsule could be recognized it is absolutely impossible to state whether it is in the stomach or in the intestines, and in what convolution of the intestine it is located.

**Exploratory Laparotomy.**—This diagnostic incision I would warmly recommend in all cases of gastric disease associated with (1) rapid emaciation; (2) absence of free HCl; (3) reduction of proteid digestion under thirty per cent.; and (4) presence of lactic acid by Uffelmann's test or (5) of numerous long baseball-bat shaped Oppler-Boas bacilli. If all of the above signs and symptoms are present in any case, even of short standing and recent beginning of the disease, and no improvement follows three weeks of appropriate treatment, I should feel justified in making the diagnosis of carcinoma of the stomach even in the absence of tumor, and urge an exploratory laparotomy.

There are in my opinion only two methods of making a possible early diagnosis of gastric carcinoma. One is curetting of the stomach, and examination of the cellular detritus and fragments of neoplasm, and seeking for evidence of mitosis, which should always suggest the possibility of a neoplasm; and the second method is exploratory laparotomy following the indications just announced. I differ from Haberkant and the other observers mentioned on the impossibility of an early diagnosis of gastric cancer. This is an altogether pessimistic view, and need not discourage the clinician.

The progress which the physiology, chemistry, pathology, and bacteriology of digestion have made in the last fifteen years, and are still making, strengthens the belief that we will be able to make an early diagnosis of gastric cancer in the near future.

## THE PARALYSES FOLLOWING GENERAL ANÆSTHESIA.[3]

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK,
CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL; ATTENDING NEUROLOGIST TO THE DEMILT DISPENSARY, ETC.

As there still seems to exist a misapprehension in regard to the etiology and character of paralytic conditions which are so often manifested after general anæsthesia for surgical purposes, a revival of this topic will not be out of place.

The facts relating to this matter are now so firmly established that it would seem to be a work of supererogation to dwell upon them, were it not that those unfamiliar with the literature of recent years adhere to the exploded doctrine that all of these paralyses are due to the toxic effect of the anæsthetic. The misleading terms "anæsthesia paralysis," "post-anæsthetic paralysis," or "post-operative paralysis," which are still in use, tend to foster such erroneous conclusions, and should, therefore, be dispensed with. In rare instances following anæsthesia, hemiplegia has been known to occur from the rupture of a cerebral blood-vessel, or a monoplegia or hemiplegia of functional (hysterical) type has shown itself.

But in the vast majority, in fact in almost every case, the paralysis is due to a lesion of the nerve trunks, the so-called "peripheral paralysis." It is always the result of direct or indirect pressure upon a nerve or nerves during the administration of the anæsthetic. Of course, we do not include cases in which the nerves are cut or otherwise injured in the field of operation. It is well known by all neurologists that in many alcoholic subjects the vulnerability of the peripheral nerves is sometimes increased to such a degree that a moderate amount of pressure over a nerve-trunk may produce numbness or tingling in its distribution. If pressure is continued, it results in one of the familiar forms of "pressure paralysis," usually involving the musculo-spiral, ulnar, or tibial nerves. Such being the case, it has been assumed that ether or chloroform also produces a toxæmia which diminishes the resistance of the peripheral nerves and renders them more susceptible to external irritation. Such a theory is inadmissible.

Few individuals during consciousness would tolerate the pain produced by persistent and continuous pressure upon the same point over one of the peripheral nerve trunks. While it is generally admitted that in alcoholic and other chronic toxic conditions the nerve trunks are abnormally sensitive, we should not seriously consider acute toxæmia as an etiological factor in cases of peripheral palsy arising as a sequence of general anæsthesia.

The paralysis produced by pressure during anæsthesia is preventable in every instance.

As a rule, it affects the upper extremities, and is occasioned by any of the following conditions:

1. Prolonged elevation and extension of the arms, allowing the head of the humerus to make pressure on the brachial plexus.

2. Metal clamps or tight straps over the shoulders or lower extremities.

3. Extension of the head toward one side, thus stretching the nerve trunks and rendering them still more susceptible to pressure.

4. Placing of the arm under the head and retaining it in the same position.

5. Permitting the arm or leg to hang over the edge of the table, thus making pressure upon some individual nerve.

6. The elbows of the anæsthetizer resting heavily in the clavicular region, pressing upon the brachial plexus.

The serious attention of surgeons should be directed to this class of cases, in view of the fact that such a paralysis may be prevented by the exercise of suitable precautions regarding the position of the patient (and the anæsthetizer) during anæsthesia. Owing to the rather common medical fallacy that a peripheral paralysis always is recovered from in a very short time, and is, therefore, of very little consequence, its real importance to the patient is either belittled or neglected. It should be borne in mind, however, that while some patients get well in a few days or weeks, in many others the paralysis may persist for months or years, and that occasionally it becomes permanent.

Its duration always depends upon the degree of injury to the nerve trunk and the recuperative capacity of the individual.

The patient I now present has a paralysis involving the brachial plexus on both sides. The following history is characteristic of this class of cases:

Miss C. D——, twenty-one years of age, first came under my care on the 29th of last August. She was subjected to the operation of vaginal hysterectomy ten weeks before. Upon recovering from the anæsthesia she was unable to use either arm, the left arm being completely paralyzed. She remained in the hospital about eight weeks. At present the right deltoid is

[2] Deutsch med. Wochenschr., 1898, No. 2.
[3] Read in abstract before the New York Neurological Society, October 3, 1899.

weak. The biceps group is markedly paretic. The supinators are feeble. The left biceps group and supinators are paralyzed. The deltoid, triceps, extensors of the hand, and the rotators of the shoulder are markedly paretic. There is some atrophy of the shoulder muscles. There is no objective sensory disturbance. Local tenderness on pressure is found in the region over the internal border of the left glenoid cavity. The paralyzed and paretic muscles are flaccid, and the faradic contractility is lost. The paralysis has persisted over three months. Fortunately she is improving, and is now on the road to complete recovery. Upon personal inquiry at the hospital I learned that during the operation she was in the "Trendelenburg position," with a strap "tightly fastened over the left shoulder.

The brilliancy of a successful abdominal operation is to a great extent neutralized by a preventable paralysis of the brachial plexus which renders the patient almost helpless for several months.

For many years I have seen several cases annually in which the musculo-spiral or other nerves have been paralyzed in this way. Since this patient has been under my care I have learned from various reliable sources that this unnecessary complication is of such common occurrence that it is usually either ignored or simply looked upon as unimportant.

The medico-legal question may arise rather unexpectedly as to the liability of the surgeon in such cases, if it can be proved that due diligence was not exercised in protecting the patient from injury during anæsthesia.

In consideration of the facts herein set forth, it is evident that suitable prophylactic measures should be instituted before the discussion of this subject undergoes transposition from the province of medicine to the arena of jurisprudence.

56 East Fifty-eighth Street.

## A PSYCHOLOGICAL STUDY OF JURORS.[1]

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

The uncertainty of jurors, and the capricious, whimsical character of their verdicts, are accepted as inevitable, and explained as part of the natural weakness of the mind. It is assumed that, if the facts are clearly presented, a jury will give a common-sense verdict, which will approximate the truth and human justice. When they fail, it is due to the confusion of testimony, the misrepresentation of counsel, and the general perversion of facts. Many thoughtful men consider the judgment of twelve men, who are disinterested, superior and on general matters of dispute of far more reliable character than the judgment of one trained man. Yet, literally, the verdicts of twelve men, based on the same set of facts, differ widely, and can never be anticipated; and, whether wise or unwise, are clearly due to other influences than the commonly supposed conflict of facts and motives of truth and justice.

While it would be difficult to doubt the motive and intent of the average juror to be just and fair in his conclusions, it would seem that certain conditions and surroundings make it impossible in most cases either to understand the case in question, or the principles of equity involved. The theoretical and ideal jury to whom are daily referred question of life and death, and often momentous interests concerning families and individuals, is never seen in real life. The delusions of the court room, that the twelve men set apart for this duty are endowed with a large and sufficient mental capacity for the discernment of justice, is far from being true in reality.

From a medical and scientific point of view, the average twelve men who are appealed to by the counsel and judge to determine wisely the issue of a case are usually incompetent naturally, and are generally placed in the worst possible conditions and surroundings to exercise even average common sense in any disputed case.

In a recent noted trial, out of a panel of one hundred jurors, twelve men were finally selected after a long, searching inquiry. Five of them were farmers, who worked hard every day in the open air, men who were unaccustomed to think or reason, except in a narrow way along their surroundings and line of work. These men all swore that they had not read any details of the case, although it occupied a large share of public attention, and had been discussed freely in all the papers. They were muscle workers, with but little mental exercise, living on coarse, healthy food, and sleeping from early evening to early morning. Of the rest of the jury, one was a blacksmith and two were mechanics, all steady workers; one was a horse trader, one a groceryman, one a retired farmer and trader, and the last man was an ex-railroad man who had no business. Every one of this jury was accustomed to be in the open air, and had not read details of the case, although he had heard it talked over. Not one of these men would have been chosen to take charge of any trust, or to decide on any matter outside of his everyday life—simply because, on general principles and from common-sense observation, he would have been clearly incompetent.

For ten days this jury was confined from five to six hours a day, listening to the testimony of the mental capacity and motives of the maker of a will that was disputed. Of course they disagreed; and had they reached a unanimous verdict, its wisdom and justice would have been a matter of accident.

In a celebrated case tried in an interior town in New York, a most complicated chain of circumstantial evidence, involving the questions of concealed motives of unusual acts and conduct, of blood-stains, of the accuracy of chemical and microscopical work, of different opinions of competent men, was submitted to a jury of the following persons: one carpenter, one wagon-maker, three coopers, two farmers, one groceryman, one contractor, and three nurserymen. These men all testified that they had not formed an opinion on the case, although it had been town talk for months. Not one of them could naturally have given an intelligent opinion on any of the issues of the case, even if they had been presented in the most impartial, simple manner by the judge. If two opposite views should be urged by opposing counsel, in an adroit, partisan manner, the most uncertain mental confusion would be inevitable.

This particular jury was not only incompetent naturally and by want of training to discriminate facts which were unfamiliar, but its members were unaccustomed to consider any range of facts compared with others to determine which were true.

In a third celebrated case, a jury composed of four fishermen, two shipbuilders, two stonecutters, one clerk, two merchants, and two persons of no business, was asked to decide on the facts of one of the most mysterious cases of poisoning. A number of expert witnesses and shrewd lawyers extended this case two weeks, and gathered a mass of statements which only the most astute judge could have disentangled. These jurymen were not only bewildered, but were mentally palsied by the appeals of counsel.

The methods of selecting jurors are thus literally open doors for the defeat of the very purposes of justice. The ostensible purpose in the selection of a

[1] Read before the Medico-Legal Society, Wednesday evening, September 26, 1899.

jury is to secure men of honesty, intelligence, and courage; to reach unbiassed conclusions in accord with the facts. In reality the practice is to gather men who can be influenced by the counsel—men possessing some defect and weakness which can be taken advantage of by one side or the other. The issue of the case will depend on the influences which can be brought to bear on the jury. Usually, jurors are rejected when they swear that they have formed an opinion; but when they assert that such opinions are subject to change from evidence and are not fixed, they are accepted. The real qualifications would seem to be availability, credulity, ignorance, and possibility of personal influence by persuasion, flattery, and appeals to some personal bias that may be known. Each counsel is interested in selecting twelve men he can influence to his view of the case, or, in the court language, "men he can handle readily." It is unfortunately true that jury duty is evaded by the best men, and to a large extent the men who are willing to serve in this capacity are more or less incompetent. In the cities, idle men and professional jurors are always available. In country towns, farmers, mechanics, and others find the jury duty a recreation, and a not unpleasant change from the monotony of their life. While these men are superior to the city jurors in honesty, they are less able or accustomed to the confinement of rooms and the emotional appeals of partisans.

It is evident to any general observation that the average jury is unable to pass judgment on, or even to comprehend in any adequate way, many of the questions submitted to it—such as motives and capacity of the mind, the power of control, the analysis of conduct, and the conditions and influences which have been dominant in certain acts; the application of the law, and the distinctions of responsibility and accountability; the distinctions of science as to the meaning of certain facts, or the recognition and discrimination of facts from the mass of statements. To this incapacity are added the passionate appeals of opposing counsel, who draw the most opposite conclusions from the same facts. Then the judge charges that if they shall find such and such conditions to be true, they shall bring in such and such a verdict; and if such and such conditions are not true another verdict must be given. This brings them into a state of the most bewildering mental confusion, from which only the trained judge could extricate himself. The wonder is that they are able to reach any verdict that even approximates the levels of human justice.

These facts are recognized by all observing men, and have been the subject of serious discussion for a long time. It has not occurred to any one to consider the conditions and surroundings of the jury who are to decide the great questions of life and death so often submitted to them. Practically and literally twelve men of uncertain intelligence, and of doubtful capacity and training essential to determine the disputed questions, are placed in the most adverse hygienic conditions for healthy brain and functional activity. Supposing these men to have fair average intelligence with honesty of purpose, they are placed always in a close, badly ventilated court-room, and are obliged to sit in one place for five or six hours a day. In cases of capital crime they are housed at some hotel at night, and have changed diet, changed sleeping-rooms, imperfect exercise, continuous mental strain, and this may be continued for a week, ten days, or even longer. Intelligent and sound brain reasoning would be impossible under these conditions. Even judges, trained to examine and reason from facts along legal lines, display weakness and confusion of mind at the close of a long trial on many occasions.

The practical observation of any jury in some important trial will show after the first day a listless abstraction that slowly deepens into a veritable mental confusion. At times, some one of the jury will appear impressed, but soon settles back into a prolonged, steady, vacant stare at the counsel and witness. As the case goes on the faces of the jurors become pale or increase in redness; their eyes lose their intelligence and become vacant or watery. Some show restlessness in their frequent changing positions of body; others become somnolent and inclined to stolidity; others are constrained, and seem to be struggling to keep up some degree of dignity, and imitate the judge in severity of manner. When the counsel flatters them, they start up anew and assume the appearance of more dignity and wisdom. Every lawyer has many curious stories of the schemes and devices to capture juries and jurors. Many of these turn on the debility and confusion of mind which come from changed surroundings and functional disorders resulting from confinement and mental exhaustion.

After the second day all connected ideas of the case become confused; only here and there some fact impresses itself, or some witticism or story that is strange or grotesque, or some conflict of lawyers, or reprimand of the judges. All the rest is vague and uncertain. The surprise on the faces of the jury, as the judge and lawyers repeat the testimony of the witnesses, shows that it is new, and that they did not hear it at the time it was given. The pleas of opposing counsel often create equal surprise in the faces of the jury. If the jury were to render a verdict after one side had closed, it would be for that side. The same conviction is noted at the close of the arguments of the opposite side. The judge's charge often dispels this conviction for the last speaker, and throws them back into more helpless, confused states. They are told to decide between this and that statement, and if they think this is true, they must find so and so; if that is true, the verdict must be so and so. In reality they have no very clear conceptions of any of the facts the judge has called to their attention. They go to the jury room in a dazed mental state, or possessed with some particular idea that has become fastened in the mind; some idea that has no logical support or sequence in the testimony which has been offered.

The following study of a case that was recently tried indicates conditions that are present far more frequently than would be supposed:

The case was murder, in which an intricate chain of circumstantial evidence pointed to one of three men as guilty. The jury was composed of five farmers, four mechanics, and three merchants. Nine of them were active muscle workers, living in the open air most of the time, and three were actively engaged indoors. The trial lasted eleven days. The jury were boarded at a hotel, and had no exercise except walking to and from the hotel to the court-room three times a day. Four of the jury complained of dull headache. On the fourth day, five of the jury had attacks of indigestion, with pain and nausea. One had chills on the night of the same day, and was given quinine freely. Two men had attacks of what was called rheumatism, consisting of pain and stiffness of the muscles, and a physician was called. Eight suffered from insomnia and constipation after the fifth night. All suffered from bad feeling and dizziness while in the court room in the afternoons. Four had coughs and colds, for which rock candy and rye whiskey were freely used. Several experienced extreme drowsiness in the court room. The arguments of counsel and the judge's charge occupied a day and a half. After the verdict and the discharge of the jury, four of them were confined to bed for several days. Here were twelve men, suffering from functional disturbances due to bad air, changed surroundings, and auto-intoxications, called to decide the issues of life and death.

In a case of murder and incendiarism in which the verdict of the jury was criticised severely, the following were the facts: The jury was composed of farmers, miners, tradesmen, and mechanics. Four of them were sufferers from cough and influenza; six complained of loss of appetite and headache; one suffered from malaria, so called; and one from a return of an old rheumatic attack. The trial lasted eight days, and most of the time the jurymen were practically sick—made so by the surroundings and changed conditions of living. The diet of hotels, consisting of rich meats and desserts in great variety, is usually different from the food of the average juryman, particularly of the working class. The result is always overeating and underexercise. This alone would quickly break up or disorder the mental activities. In addition to this, the confinement in the bad air of the court-rooms brings new sources of poisoning, particularly deficient oxidation, which of itself is sufficient to derange the normal brain functions. The crowded rooms at hotels are either overheated and badly ventilated, or cold and noisy. The time for retiring and rising varies, and the usual habits of the juryman are changed in every respect. His accustomed food, sleep, and exercise, and his manner of thinking and the subject of his thoughts, all are broken up. He is asked to follow an intricate chain of reasoning, and discriminate the errors, and told that this is true and that is true, and that the law should lead him to some other point. He is flattered, and his pride is roused to do the best he can. He grows more incapacitated daily as the evidence accumulates, and his system becomes deranged. Then, in despair, he will suddenly form some conclusion, guided by a fancy for some attorney or some remark by the judge. Perhaps a stubborn member of the jury has formed a conviction on the first day of the trial, and all the rest of the time is passed unconscious of evidence, *pro* or *con*, and in the jury-room his very stubbornness wins.

In a noted murder trial at Portland Me., it was evident that the jury had been impressed favorably to the prisoner. The prosecuting attorney suggested to the sheriff that he invite the jury to church Sunday evening to hear a noted preacher. The topic of the clergyman was "God's Hatred of Sin, and Divine Judgment." The attorney knew the topic and the intense dogmatism of the preacher, and calculated its effect on the jury. A verdict for conviction followed, due almost entirely to the sermon.

The personal characteristics of the jury are often the only doors through which they can be influenced. Religious, political, and social or personal prejudices are often considered by counsel in the presentation of the evidence. In reality, the average juryman becomes more incapacitated to rise above his prejudices, or to reason impartially, every day he is confined to the court-room. At the end of a long trial he is utterly unable to form any new views, and nothing remains but his old prejudices, and these are often more fixed than ever.

The following record of a juryman's experience was made by a carpenter of more than average intelligence. He put down each night his impressions: The first day he was impressed with the magnitude of the case and the sadness of the prisoner. He did not sleep the first night, for the reason that four men occupied one room. The air was bad, and two men snored loudly. The second day he tried to remember all that the witnesses said, and its bearing on the case, and at night was very weary and went to bed early, but was wakened and disturbed by the other jurors. The third day his head ached, and he could with difficulty follow the testimony. His appetite was poor and he was drowsy. The fourth day he was astonished to hear opposing evidence; statements which had been made by apparently honest men were affirmed to be false. He was shocked, and his first impressions and personal interest were disturbed. His head ached, and he felt weak and nervous; his appetite and sleep were broken. The fifth day he gave up all efforts to follow the testimony, or to understand what was said. He felt stupid and excessively tired. The other jurors began to complain of the food and sleeping-rooms, and had several quarrels with each other on religious and political matters. Foolish stories were told, and card-playing and personal boasting filled up the evenings. They all manifested disgust at the trial, and longed for the end, and declared they would never be caught in a similar case. On the sixth day the case was closed. The arguments of attorneys and the judge's charge seemed very dull and wearisome. He felt sick, looked forward to a release, and his interest in the case died out. He could not understand why so much was said that was contradictory, and why the judge should not tell them the real facts of the case. In the jury-room no discussion took place: each one voted "guilty" or "not guilty"; and when they found the majority was "guilty," most of them followed the majority. Two of the minority became angry, and refused to vote for over a day, except in favor of the prisoner. They gave no reasons for their belief, only saying that they were right and the rest of the jury were wrong. Finally, one of these men was accused of having some personal object in voting for the prisoner, and after a short altercation he changed, and the other man followed him, and the verdict of "guilty" was agreed upon.

In my experience as an expert witness I have frequently noted the changes of feelings in a moderate-drinking juror. If the prisoner is an inebriate, and the crime associated with excessive use of alcohol, the first two days of the trial all moderate-drinking jurymen manifest strong feeling for the prisoner. Later, when they become tired, dull, and debilitated by the surroundings, all this feeling changes to severity and desire to punish, no matter what the evidence may be. All natural sentiments of sympathy and kindness are replaced by the coarser, lower motives, as the brain becomes disordered and weakened. If any of the jury have had a similar weakness or committed crime while drinking, they usually urge most severe punishment, and especially after they lose their mental vigor in the bad air of the court-room. In some cases the opposite prevails, and jurors are strangely stubborn in their unreasoning convictions for the prisoner. This is naturally the outcome of placing untrained men in positions which they cannot fill, and requiring of them clear judgment under circumstances in which it is almost impossible to act normally.

## RENAL CASTS—THEIR SIGNIFICANCE AND DETECTION.[1]

By JO. H. LINSLEY, M D.,

BURLINGTON, VT

DIRECTOR OF THE LABORATORY OF HYGIENE, VERMONT STATE BOARD OF HEALTH.

Mr. President and Gentlemen: If any apology is thought due this assemblage for the consideration of such a well-worn theme as that of my text it is to be found in the belief entertained by the speaker, after an experience of nearly twenty years in the chemical and microscopical examination of urine, that in our northern latitudes there is no disease so frequently undetermined in its incipiency as chronic Bright's disease. I refer particularly to that form described under various titles, as chronic interstitial nephritis, chronic productive (or diffuse) nephritis without exu-

[1] Read before the Connecticut River Valley Medical Association, September 19, 1899.

dation, chronic Bright's, cirrhosis of kidney, granular degeneration, chronic indurative nephritis, the arteriosclerotic kidney, gouty kidney, small granular kidney, etc.

This disease occurs frequently about middle adult life, is found in apparently strong, healthy, and well-nourished individuals, and is one of the most insidious of all physical derangements. In the great majority of cases it is well advanced before it is detected, and in many cases even before the advice of a physician is sought.

Among the first symptoms noticed are a tendency to micturate once or twice during the night, slight disturbances of digestion, very slight dyspnœa on exercise. There may or may not be headache, which is not confined to any particular portion of the head. If the person is one of nervous temperament there is apt to be more or less neuralgia in various parts of the body. The urine at this time may be normal in quantity, color specific gravity, and reaction. The amount of urea excreted may be normal or only slightly below the average amount, and the other solids entirely normal. Generally there is no albumin or peptone, although occasionally there is a mere trace ($\frac{1}{10}$ of one per cent. by weight, or less) of the former.

The only sediment observable to the unaided eye is the usual light—nearly transparent—cloud of mucus, which appears just below the middle of the fluid after the urine has stood in a conical glass, or beaker, for an hour or two. After standing in such a glass vessel a few hours—or, better still, after sedimentation with a centrifuge—if some of the sediment is placed under the microscope, and the instrument manipulated as will be described later, a greater or less number of hyaline casts will be seen, generally a few uric-acid crystals and crystals of calcium oxalate, often a few scattering red blood cells, a greater or less number of leucocytes and squamous and possibly some round epithelia. The hyaline casts may be very few in number, not more than five or six being seen in the preparation; but these and the blood cells are of the greatest significance.

As it is the former which I wish to consider in this paper, and as I have often found some confusion in the minds of medical men as to the formation and structure of renal casts, I trust you will pardon me if I briefly refer to the structure of the kidney, or particularly to that portion of it known as the tubules. A renal tubule, as you all know, commences as a small round body—Malpighian body—found in the cortex, commencing just beneath the capsule. This body is approximately $\frac{1}{120}$ inch in diameter and consists of the loop of blood capillaries from the afferent vessel and extending around this loop (except where the blood-vessel enters and passes out), a delicate structure consisting of a basement membrane and a single layer of flat epithelial cells, at a point opposite the entrance and exit of the afferent and efferent blood-vessels respectively is a constricted portion, or neck, after which follow in succession: proximal convoluted tube, about $\frac{1}{600}$ inch; spiral tube, about $\frac{1}{3000}$ inch; Henle's loop (descending portion about $\frac{1}{1200}$ inch, ascending portion about $\frac{1}{800}$ inch); irregular tube about $\frac{1}{6000}$ inch; distal convoluted tube about $\frac{1}{6000}$ inch; arched collecting, larger; straight collecting, larger, excretory ducts, larger. The only portions of this tubule known to possess the power of true secretion are the convoluted, spiral, and irregular tubules. These portions are lined with irregularly triangular cells, having very minute striæ, or channels, running through their longest diameter. They were formerly called the "rodded cells of Heidenhain." All the other cells of the tubules are either flat, nearly columnar, or of shapes intermediate between these two.

It is the pretty generally accepted theory that the lining membrane of the Malpighian body, or Bowman's capsule, acts primarily and principally as a filter, allowing the passage of water in which the sodium chloride and probably some of the other inorganic salts are dissolved, but in its normal condition opposing an effective barrier against the transmission of urea and all organic constituents. The latter are eliminated in the convoluted, spiral, and irregular tubules by a process of true secretion. In health the walls of all of these tubules will allow the passing through them of none of the albuminous constituents of the blood plasma. If, however, there is impaired nutrition, excessive pressure in the area of the renal artery, or any degeneration of the basement membrane or lining cells, these cells may not be able to prevent some of the blood plasma from passing through the walls of the tubules and thus into their lumina. The tendency of blood-serum when forced or passed from the blood-vessels is to coagulate. This is what happens in our uriniferous tubule after the serous exudation, the result being the formation of a plug, which, when washed or flushed out of the tubule by the pressure of the urine secreted behind the obstruction, appears in the voided urine as a small, clear, very slightly refractive cylinder, or hyaline cast. This hyaline cast furnishes the basis, or foundation, for several other varieties of casts, which are named according to the material adhering to—or contained in the substance of—the hyaline cylinder. Thus if small, round epithelial cells are found adhering to the cast it is called "epithelial"; if finer or coarser granules are contained in the cylinder, these adjectives are employed to describe it. In the case of blood casts, if the hemorrhage is an active one the groundwork of the cylinder is composed of fibrin—if of a passive character, of hyaline albuminoid material.

When there is a considerable and rapid exudation of leucocytes into the tubules a plug, or cast, composed practically entirely of these cells is produced. In some septic diseases of the kidneys casts consisting almost entirely of bacteria are seen. Fatty casts are often met with in the acute infectious fevers and in poisoning with some mineral substances, they seeming to be a frequent result of toxæmia.

The following varieties of casts have been found:

Hyaline: Narrow or broad.

Granular: Narrow, finely granular; broad, coarsely granular.

Epithelial: Generally narrow; rarely broad.

Mixed: Epithelial and granular; usually narrow: exceptionally broad.

Blood: If from nephritis, narrow; if from trauma, may be broad.

Fibrin: Of same significance as last.

Pus: May be narrow or broad.

Fatty: Narrow or broad.

Bacterial: Narrow or broad.

Waxy: Narrow or broad.

Cylindroids: An irregular hyaline cast: usually narrow, often somewhat ribbon-shaped, especially at one end.

In considering the significance of the presence of renal casts it is well to remember that these bodies when formed beyond the irregular tubule are never discharged with the urine, as we have seen that the calibre of the ascending limb of Henle's loop is too small to allow of the passage of any body whose diameter is that of the preceding divisions of the uriniferous tubules except the descending limb of Henle's loop.

Much has been written concerning the significance to be deduced from the presence of "broad" casts in comparison with those usually described as "small" or narrow. I believe there are two plausible theories to account for the presence of the larger casts.

The first is that they originate in the excretory ducts, or collecting tubes, the diameter of which is greater than that of the tube beyond; the second that they come from tubules the lining epithelium of which has been desquamated, thus having a tubule whose diameter has been increased by the amount of epithelium removed. It will be seen that either of these views warrants the belief generally held that the presence of broad casts is indicative of a more grave condition than that represented by the small or narrow ones.

Small or narrow hyaline casts: The least significance of the presence of these casts in the urine is renal irritation; the greatest, advanced chronic interstitial nephritis.

Notwithstanding the statement of many medical men whose opinion is generally of weight to the contrary, the occurrence of these cylinders, even if very few in number, should put the physician on guard, and the urine of his patient should be subjected to critical examination at regular intervals until these bodies have disappeared from the renal secretion. I am convinced that many cases of so-called Bright's disease exist for months without detection, simply because a careful microscopical examination of the urine is not made, the chemical analysis of such a specimen being entirely negative.

As one of the common causes of the presence in the urine of small hyaline casts may be mentioned the excretion of uric acid, the irritation of the kidneys by the secretion of the acid producing the exudation of more or less serum through the walls of the tubules. Indeed I do not now recall a specimen in which, when this substance was present, there was not found by careful examination a greater or less number of these casts. And this so-called uric-acid diathesis is, as you well know, very commonly a pre-nephritic condition. I believe if the importance of recognizing and properly treating this state of mal-nutrition—for it is practically nothing else—was more generally observed, we would annually save many lives which now succumb to renal cirrhosis.

Granular casts: These cylinders appear in a variety of conditions, showing all grades of granulation from light finely granular to dark coarsely granular casts. The granules are due to disintegration of the protoplasm of the lining epithelial cells, blood and pus corpuscles, and other anatomical elements. They consequently represent a nephritis of some little standing and also indicate an involvement of the parenchyma of the kidney rather than its stroma, though, of course, both may be and usually are implicated sooner or later, especially if the disease commences as a parenchymatous lesion.

The coarse granules found in this variety of cast are supposed by some to represent the nuclei of epithelial cells which have undergone rapid disintegration, and hence are thought to indicate an acute process. These cylinders ordinarily are not so long as the hyaline.

Epithelial casts are exceedingly important as being positive evidence of an acute parenchymatous inflammation. They may contain dark and fatty granules or leucocytes, and are more resistant to the action of chemical reagents than all other renal cylinders with the possible exception of those of a fatty nature.

Mixed casts are to be considered as having the same diagnostic value as the epithelial ones.

Renal casts composed of blood or fibrin do not prove the existence of organic disease of the kidney, but are to be accepted as perhaps the only reliable evidence of renal hemorrhage. They are found after injuries to the kidney, congestion of that organ, especially if acute, acute diffuse nephritis, hemorrhagic infarct of the kidney, and in malignant growths of the kidney causing a destruction of the vascular walls.

Pus cylinders are comparatively rare and have been described in the books to my knowledge only within a few years. I have seen several cases having this condition. They may be found in multiple renal abscesses, pyelo-nephritis, and, I believe, in almost any suppurative process involving the parenchyma of the organ.

Fatty casts, representing as they do an extremely active degeneration of protoplasm, show either an extreme chronicity or the effect of an active toxic agent, be that agent of inorganic or organic (principally bacterial) origin. In the majority of cases a more or less severe toxæmia will be found to exist.

Casts composed of bacteria may be found in cases of septic nephritis, such as pyelo-nephritis, and are said to be (Purdy) often accompanied by embolism. Their import is grave.

In various infective diseases such as tuberculosis, carcinoma, sometimes in syphilis, and after the ingestion of certain poisons—notably phosphorus—there frequently appear in the urine highly refractive, narrow or broad, short or long, peculiarly indented cylinders—the so-called waxy or amyloid casts. Purdy classifies these bodies with the hyaline variety, but as their significance is entirely different from that variety of casts, I think their importance demands independent consideration. While their name indicates a starchy composition, it is only used to denote the similar reaction with iodine which the substance composing these casts exhibit; starch *per se* never having been demonstrated to occur in them.

Cylindroids: Two classes of these bodies are found in urine: One, coming from the kidneys, is long or short, narrow or broad, but at some portion gives the rounded, cylinder-like appearance characteristic of hyaline casts. Usually, one extremity of these cylindroids tapers to a fine end and has a flat appearance; it is often wavy, or contorted, at this portion. They are generally longer than the hyaline cylinders and have the same significance as these bodies.

The second, probably originating in the ducts of mucous and other glands found along the genito-urinary mucosa, are distinctly ribbon-shaped, or flat, throughout, at no place showing the cylinder-like appearance just mentioned. They have no significance as bearing upon renal disease.

**Detection of Casts.**—Before examining a urine for casts it should either be allowed to stand in a covered conical glass for at least three hours, or, what is better, subjected to mechanical sedimentation in a centrifuge. The latter has the advantage of allowing an inspection of the sediment in a fresh state, an important matter when dealing with a very acid or alkaline urine, and also saves valuable time to the investigator.

Whether obtained by either of these methods, a small portion (a few drops) of the urine from the bottom of the fluid, and which contains the sediment, is removed with a pipette and placed on a clean glass slide. No cover-glass is used in this manipulation. The slide containing the specimen is then placed on the stage of a microscope and a ¾-inch or ½-inch (No. 2 or No. 4) objective brought into the optical axis of the instrument. A higher power of the microscope should never be used for the detection of casts in the urine. The next step, the illumination of the specimen, is so important a procedure that without careful attention to the details of its application no casts will be seen, even though there be hundreds of them on the glass slide under observation. Proceed as follows: reduce the opening in the diaphragm until the specimen is only faintly illumined; turn the mirror, using its concave side, in such a way as to direct oblique rays of light through the slide and objective. The manipulation is extremely simple and can be acquired in a very short time by any one at all con-

versant with the use of the microscope, yet I have seen a surprisingly large number of failures to detect hyaline casts in a urine containing them in abundance, because of the non-observance of the methods detailed.

When hyaline casts are present in a specimen which has been mounted in this manner they appear as sharply defined, somewhat refractive, and perfectly transparent diminutive logs with rounded ends.

After carefully examining the specimen with the low power, a cover-glass may be applied, the superfluous urine removed with a piece of blotting, or filter, paper, and the specimen investigated with a $\frac{1}{3}$-inch or $\frac{1}{5}$-inch (No. 5 or No. 7) objective. In this case more light is needed, and the opening in the diaphragm must be enlarged. The higher magnifying power allows the study of the structure of any casts or epithelial cells, and the detection of pus or blood cells and bacteria, but it should never be employed until after a thorough examination with the low power.

I might call your attention to the fact that in many cases of Bright's disease the patient will void urine which may be free of any evidence of the disease, hence the very great necessity of subjecting a sample of the mixed twenty-four hours' urine for analysis.

As illustrating the importance of a microscopical examination of urine in determining any renal trouble, I will detail the urinary findings and condition of a person under observation at the present time, and which is only one of many similar cases which I have seen:

Male, aged forty years, six feet in height, weight about two hundred pounds, in perfect health up to within a few weeks, when he complained of neuralgic pains in head and extremities, lassitude, some disturbance of digestion; very little anorexia. He complains of restlessness at night. He had no alcoholic or specific history.

Urine, quantity in twenty-four hours, 40 ounces. Color, reddish-yellow; clear; acid in reaction; specific gravity 1.020; total solids, 880 grains; urea 9¼ grains to the ounce, 370 grains in twenty-four hours; chlorides, normal; phosphates, slightly decreased. There was no albumin or sugar. Microscopically were found numerous hyaline, slightly granular, and epithelial casts, a few colored blood cells, a few leucocytes, a few squamous and round epithelia, and a few uric-acid crystals. Since the first analysis, some two weeks since, this has been the average condition of the urine, with one exception when there was the faintest trace of albumin discoverable by ordinary tests. The amount of urea has considerably increased since the first examination, and is now about normal. To all external appearances the urine was a perfectly normal specimen, and unless a microscopical examination had been made as a part of the regular and invariable routine in such examinations, the condition of the kidneys would have entirely escaped observation, and the continued congestion of these organs would almost surely have resulted in interstitial changes in the renal tissue.

**Adenoma of the Breasts.**—The following points were emphasized by Dr. L. A. Balloch (*American Journal of Obstetrics*): (1) Adenomata are not the harmless growths that many believe them to be, and there is a great probability that they may and do become cancerous. (2) The let-alone and do-nothing policy is to be condemned. (3) Medicinal therapeutics, internal and external, are useless. (4) Early recourse to the knife affords a safe and satisfactory method of dealing with them, and will often spare us the mortification of seeing our patients fall into the hands of charlatans.

## Progress of Medical Science.

**Exstrophy of the Bladder.**—Dr. Rudolph Matas (*Journal of the American Medical Association*, July 29th) summarizes his impressions of the operative treatment of bladder exstrophy with special reference to Maydl's operation, as follows: (1) All autoplastic methods proposed for the cure of exstrophy of the bladder are unsatisfactory and, at best, simply palliative. (2) Of all the radical methods which involve an excision of the bladder and a transplantation of the ureters to the rectum, Maydl's operation is by far the most complete, rational, and satisfactory from the technical point of view. (3) Maydl's operation offers the best conditions for the correction of the associated epispadias. (4) Notwithstanding the comparatively large number of successful cases accredited to this method, its relation is not fully ascertained, though the ratio, as obtained from published cases—over thirteen per cent.—establishes the superiority of this method above all others from the prognostic point of view. (5) Notwithstanding the apparent theoretic simplicity of its technique, Maydl's operation is a difficult, laborious, and in many respects a dangerous operation, and should be undertaken only by those who have thoroughly familiarized themselves with its difficulties by special training in abdominal surgery, supplemented, if possible, by experimental work. (6) It should not be applied indiscriminately to all cases, but only to those patients whose general condition is such as to warrant a long, tedious operation likely to be attended by serious shock; and whose eliminating organs, especially the kidneys, are normal and capable of effective elimination.

**Degeneration of Medullated Nerve Fibres.**—G. Monckeberg and A. Bethe detail in the *Archiv für mikroskopische Anatomie und Entwicklungsgeschichte*, vol. 54, 1899, some results by new methods of investigation on the characters of the normal primitive fibrillæ in nerve fibres in various animals and their pathological alterations. By a series of fixation experiments on egg albumen by osmic acid, already more carefully and widely done by Butschli and others, they show that that fixative is an ideal one, in that it shows no peculiar reticulations when treated by other reagents, and hence conclude that it has a like action on nervous protoplasm and thus can give no artefacts. They overcome the difficulties of poor staining qualities following such treatment by some reducing agent. They claim that the axis cylinder of medullated nerve fibres in vertebrates consists of sharply outlined individual primitive fibrillæ and a homogenous perifibrillar substance surrounding them. Every primitive fibril maintains throughout the nerve fibre a uniform calibre and shows no swellings at the nodes of Ranvier. At such nodes the perifibrillary substance is totally absent, and thus it, as a conducting element, has no place. The sheath of Schwann, although it sends down processes at the nodes of Ranvier, is also broken by these in much the same manner that the myelin sheath is segmented. An especial arrangement exists at the nodes to guarantee the isolation of the fibrillæ. The first sign of degeneration in a nerve, following its solution of continuity, is a diminution in the primary staining qualities of these primitive fibrils; following this there results a degeneration of the fibrils themselves. By this degeneration these fibrils form large granular bodies, which break down into smaller ones and are finally absorbed. The previously homogeneous perifibrillary substance shows granular changes. The degeneration does not take place all at one time, but follows regularly from the site of the trauma

toward the periphery and toward the centre. In the peripheral end the degeneration is total, but for the central portion it is only partial, though single fibrils may degenerate throughout. Sensory fibres degenerate faster than motor fibres. The authors could find no distinctions for primary or secondary degenerations. The paper is illustrated with suggestive figures.

**A Method of Demonstrating Fibrillæ in Pathological Specimens of Nerve Tissues.**—The new researches of Apathy and Bethe have brought into prominence the older views of Schultze on the structure of the nerve fibres, and modern histological technique is busy with methods for demonstrating the newer points of view. Bethe describes, in the *Archiv fur mikroskopische Anatomie*, May 19, 1899, a method especially applicable, he believes, to pathological material. He first fixes the nerve fibres, for twenty-four hours, in osmic acid—the strands of fibres should not be more than 1 mm. thick; large trunks should not be used. They are washed in water from four to six hours; in alcohol, ninety per cent., ten hours or more; in water four hours; six to twelve hours in a two-per-cent. solution of sodium bisulphate, to every 10 cc. of which two to four drops of concentrated hydrochloric acid have been added just before using. They are washed again for from one to two hours, then placed in alcohol, xylol, paraffin, and embeded. Specimens should be cut as thin as possible—2 to 3 mm.—and these are then fastened to the slide by an albumin fixative. Staining may be direct or indirect. Direct method: 0.1 per cent. aqueous solution toluidin blue, warmed to 50–60° C., for ten minutes. Wash with water and then fix for a few seconds to a minute in a one-per-cent. solution of ammonium molybdate. Mount in balsam.

Indirect method: Place the slides in 0.25-per-cent. solution of ammonium molybdate at a temperature of 20–30° C. for from five to ten minutes. Wash five or six times rapidly in cold water. Stain with toluidin or methylene blue, 0.05–0.1 per cent., for five minutes at a temperature of 50–60° C. Wash in water, alcohol, xylol, and balsam. The process is simple and comparatively rapid, and gives excellent results, according to Bethe.

**Metabolism and Diphtheria.**—Infective febrile processes are not always accompanied by high temperatures, but when present it is pretty universally admitted that such elevations are due to the toxic action of micro-organisms. Von Noorden, in his "Pathologie des Stoffwechsels," has shown how much there is to be investigated in elucidation of many of the questions of tissue change in such conditions. With the idea to clear up some questions, Noel Paton, J. Dunlop, and Ivison Macadam, in the research laboratory of Edinburgh (*Journal of Physiology*, July 28, 1899) undertook a series of experiments on dogs. The dogs were placed upon a fixed diet for some days to establish a balance in their eliminated products; were then subjected to a one day's fast and then three days again on the same diet, after which a given dose of diphtheria toxin was administered and the metabolism in the normal condition compared with that of the artificially induced febrile condition. The urine and fæces and expired air were collected, and chemical analyses of an extended character were made. The collected results warranted the following conclusions: Under the influence of diphtheria toxin in the dog, there is no interference with the digestion and absorption of proteids. There is a marked increase in the proteid katabolism, probably as a result of a direct toxic action on the protoplasm. There is an interference with the elaboration of waste nitrogen into urea which leads to an increase in the proportion of nitrogen, not as urea, in the urine. No marked increase in the proportion of nitrogen to ammonia occurs. The excretion of uric acid is not manifestly modified. The excretion of sulphuric acid is not increased proportionately to the increased excretion of nitrogen. The total excretion of sulphur bears a fair proportion to the excretion of nitrogen. The neutral sulphur—sulphur not as sulphates—is increased, probably by an interference with its oxidation to sulphuric acid. The absence of an increase in the formation of sulphuric acid probably explains the absence of an increased formation of ammonia. The diminished elaboration of sulphur into sulphuric acid appears to be connected with the diminished elaboration of nitrogen into urea. Both are probably due to to an interference with the hepatic function similar to that already demonstrated to occur in febrile conditions in the manufacture of the bile constituents. The excretion of phosphorus is not increased, but is lower in fasting with fever than in fasting alone. The proportion of phosphoric acid to nitrogen is markedly diminished. This would seem to indicate the absence of any increase in the katabolism of nucleins as compared with other proteids. The absence of any relationship between the phosphoric acid and the nitrogen not as urea seems to militate against the view that the purin bases which contain part of that nitrogen are necessarily derived from nucleins. There is no marked alteration in the proportion of potassium and sodium such as was observed by Salkowski in febrile conditions in man. This may possibly be explained by the different distribution of the two bases in the red blood corpuscles of man and of the dog. The excretion of chlorine is markedly diminished actually, in proportion to the excretion of nitrogen, and most markedly in proportion to the excretion of sodium and potassium. This alteration in the proportionate excretion of chlorine and of these bases raises the question as to the nature of the chlorine compounds of the tissues, and suggests that in the body chloride of sodium may be split up elsewhere than in the gastric mucosa. The question of what acid takes the place of hydrochloric acid in combining with the bases in the urine is not elucidated.

**Soap Cysts of the Mammary Gland.**—Milk and butter cysts of the mammary gland are described, but they belong to the rarer manifestations of pathological mammary developments. Freund describes (*Virchow's Archiv*, 1899, vol. 156, No. 1) a cyst about four by three inches, which on section was found to contain soapy masses. These on chemical examination proved to be real soaps made by the salts of calcium and magnesium, in combination, not with milk or butter, but with the products of a fatty degeneration of the fibro-adenoma, to which anatomical variety the cyst belonged.

**Gangrene of the Lung.**—A. H. Levings (*New York Medical Journal*, October 14th), in an interesting article on this subject, gives the dangers and complications which may arise during, or as a result of, surgical intervention as follows: (1) Suffocation. In any patient having a cavity more or less filled with fluid and in direct communication with a bronchus, there is a real danger of suffocation during the administration of an anæsthetic. (2) Some of the septic material may be inspired, setting up a fetid bronchitis. (3) The danger of shock and the subsequent exhaustion is very considerable. (4) Hemorrhage, both intercostal and pulmonary, may occur. (5) Septic infection of healthy lung tissue as the result of a puncture may take place. (6) Operative interference may be the cause of secondary rapid sloughing, and gangrene of the lung may follow interference when adhesions are absent or insufficient. (7) Pneumothorax and pyopneumothorax. The points he desired to make were these: (1) All

cases of pulmonary gangrene which are progressive and not absolutely diffuse should be operated upon. (2) The gangrenous area should be localized by physical examination, aided by the use of the aspirating needle, and, if necessary, by multiple resection of ribs. (3) In the absence of pleuritic adhesions, the general pleural cavity should be shut off either by a gauze packing or by a row of sutures. (4) After thorough opening and free drainage of the gangrenous cavity it should be daily cleansed by gentle irrigation. (5) The cavity should be tightly packed with iodoform gauze.

**Toxic Erythema.**—Kaposi (*Allgem. Wien. med. Zeit.*, September 19th) relates an instance of death following a generalized purpuric erythema in spots of the dimension of twenty-five and fifty-cent pieces. There were marked prostration and bronchial irritation suggesting that a similar outbreak affected the mucous membrane, since blotches could be seen in the mouth and pharynx as well as upon the conjunctiva. The toxic agent could not be discovered. Death occurred on the tenth day after a slight improvement in the symptoms had been noted.

**Distoma Heterophyes** in a living subject is reported by Dr. Sandwith, of Cairo (*The Lancet*, September 30th). Half a century ago the distomum was found post mortem, and since then little attention has been given the question until 1894, when Dr. Looss wrote upon its occurrence in Egypt. There were no symptoms attributed to this most minute fluke, and the case is reported because of its previously exclusive post-mortem interest.

**The Early Diagnosis of Myxœdema.**—Charles W. Chapman (*The Lancet*, September 30th), regarding the early diagnosis of myxœdema, says: "I will conclude by calling attention to a diagnostic sign in early myxœdema which has proven useful. In chronic renal disease an early sign, when looked out for, is a certain sloppiness of the conjunctivæ which is best observed by pushing up the lower eyelid at the outer angle of the eye. This is known as the 'Bright's eye.' In myxœdema the same condition exists caused by the presence of mucin. When I find the conjunctivæ thus affected without any local cause I invariably examine the urine, and when this fluid is of normal specific gravity and is devoid of albumin I look out for myxœdema. I have more than once been put on the right track by these means."

**The Sequelæ of Iritis.**—Charles D. G. Hailes (*Edinburgh Medical Journal*, October), in an article entitled "The Clinical Aspects of Iritis," says: "The sequelæ of iritis, when treatment has been omitted or begun too late, are: (1) formation of posterior synechiæ binding down the margin of the iris, so that the mobility of the pupil is interfered with; (2) occlusion of the pupil, or filling in of the pupillary space with membrane formed from the inflammatory exudates, causing permanent dimness of vision, but, if incomplete, dangerous; (3) exclusion of the pupil, with iris bombé, not necessarily causing dimness of vision, if the pupillary area be free, but interfering with the escape of fluid into the canal of Schlemm, giving rise to excess of tension, and destructive glaucoma is always to be feared as a further complication; (4) total posterior synechiæ, with cyclitis, is always present, followed by disorganization of the globe."

**Trophic Pemphigus.**—Lalanne publishes an instance of pemphigus in a subject of general paralysis, followed by a suppurating dermatitis. There was a prodromal period and preceding vomiting. An erythematous plaque appeared which became rapidly bullous; at first the fluid was rose-colored, then violaceous, and finally purulent with secretion of thick pus becoming greenish-yellow. The course was progressive with extensive ulceration. Following the outbreak there was an infectious dermatitis (pustules with turbid contents) transmitted to the ward nurse. The pustules after abundant discharge dried up and ended in desquamation of the raised epidermis. Although the patient was regarded as syphilitic, the eruption was believed to be of trophic origin, chiefly for the reason that specific pemphigus is only encountered in young infants, or in the adult occupies the palms and soles.—*Le Progrès Médical*, September 23d.

**Abortion of Uncomplicated Immature Cataract by Combined Manipulation and Instillation.**—Dr. Richard Kalish (*Medical News*, October 14th) summarizes an article on this subject as follows: (1) Immature cataract is due to local conditions dependent upon general systemic causes. (2) Senility is rarely a direct, but may be a predisposing, cause. (3) Fluids containing perverted aliments resulting from defective metabolism supplied to the lens through its nutritive stream may be considered an exciting cause. (4) Deficient blood supply, thus reducing the quantity furnished, may be considered a contributing cause. The following conclusions may be drawn: (1) Immature cataract may be regarded as a largely preventable disease. (2) It may, by properly directed treatment, local and constitutional, be arrested, retarded, or cured. (3) The circulation of the blood must be regulated. (4) The faulty digestion must be rectified. (5) Constant supervision of the eye must be maintained by a competent ophthalmologist, that eye strain may be relieved, and all changes in refraction be promptly remedied. (6) Treatment by conjoined manipulation and instillation should be instituted at the earliest possible moment. (7) Finally, if local and constitutional treatment should not provoke a favorable issue they will establish a more nearly normal state of the ocular tissues, and if an early operation be found necessary, this improved condition of the ocular structures will insure a larger degree of success.

**The Present Position of the Neuron Theory.**—Hoche, of Strasburg, before the annual meeting of German alienists at Halle (*Centralblatt für Nervenheilkunde und Psychiatrie*, vol. 22, 1899), gives a critical résumé of the present status of the neuron theory. He holds (1) that the conception of the neuron, in the full sense outlined by Waldeyer, is no longer tenable; (2) the truth of the fibrillar theories of Apathy and Bethe does not interfere with the embryological data on the individuality of the nerve cell; (3) the histological individuality of the neuron is, in developed vertebrates, no longer to be held; (4) the experiences of human and animal experimental pathology show that there is a trophic and functional individuality in the neuron, even if the evidence for such histological unity is lacking.

**The Testicles and Phosphoric-Acid Metabolism.**—That the testicles are important elements in the elimination of the phosphorus compounds of the body is evidenced by the recent experiments of Schultz and Falk (Hoppe-Seyler's *Zeitschrift für physiologische Chemie*, 27, 1899, p. 250). These observers found that following castration in the dog there was a marked retention in the body of the phosphoric-acid derivatives, as well as marked qualitative changes in that part of the nuclein and nucleo-proteid derivatives eliminated by the urine.

**On the Relation of Epilepsy to Sleep.**—A. Pick, of Prague (*Wiener med. Wochenschrift*, 1899, No. 30), gives some interesting measurements of the blood

pressure during the condition of sleep, and attempts to draw some inferences from them with reference to nocturnal epilepsy. He states that, since two-thirds of all epileptic attacks are apt to occur in sleep (a statement that needs more extensive material, such as is to be found in the Craig Colony statistics, to be accepted), and most of these occur either within the first hour after sleeping or just before awakening, or some in the deepest sleep, plethysmographic tracings of the blood pressure have shown that just at such times there is the least quantity of blood circulating in the vessels of the brain. He further observes that perhaps such a quantitative variation in the amount of blood flowing into the brain may constitute one of the factors that render the bringing about of an epileptic attack probable.

**Renal Semiology.**—Dr. L. Suarez (*Annales des Maladies des Organes Génito-Urinaires*, September) presents a paper in which he states his belief that a large number of chronic catarrhs of the bladder which do not correspond to any of the known causes (prostatitis, stricture, calculus, tuberculosis, etc.) are in reality due to pyelitis, or pyelo-nephritis, of rapid development, giving symptoms worthy of attracting attention. In conclusion he says that in these cases a cystoscopic examination should always be made if it is possible, and if no lesion is found in the bladder the ureters should be catheterized. In suppurative lesions of the kidney, the ureters should be catheterized if possible and the test made of permeability at the same time with methylene blue, reserving the cause and the class of intervention for the moment of operation.

**Vanadium Medication.**—Létienne (*Archives Générales de Médecine*, September, 1899) reports upon the action of the salts of vanadium, and more recently Berthail (Thèse de Paris, 1899) gives his experiences with some one hundred and fifty cases with the preparations of this metal. The salts of sodium, lithium, and iron have been most extensively employed and also the phospho-vanadate of sodium. Berthail concludes that apart from some transitory gastric disturbance and at times a fugitive diarrhœa no harmful after-effects are to be encountered in the use of these preparations. Most of the Lyons observers have found that the best vehicle for these is water, and the dose is about gr. $\frac{1}{6}$ to i. in the twenty-four hours. The indications which are marked are for the treatment of the lithæmic and gouty diathesis and for diabetes. Neurasthenia is also helped. In gout the subacute arthritic pains are markedly relieved, and in diabetes the glycosuria has been known to disappear entirely. The urea is increased, showing the oxydizing action of the drug. The phospho-vanadate of sodium is of especial service in the treatment of neurasthenia. The reports also would indicate that the drug was of limited applicability in the treatment of malaria and of certain skin affections due to poor general metabolism.

**Elimination of Methylene Blue.**—A series of observations were conducted by V. Czyhlarz and Donath on the eliminating powers of healthy and of diseased kidneys (*Wiener med. Wochenschrift*, No. 28, 1899). Eighteen subjects having healthy kidneys were experimented upon, as were also eighteen patients suffering from Bright's disease and three cardiac patients showing albuminuria. In two instances only out of six cases of interstitial nephritis with contracted kidney was there a delayed appearance of chromogen in the urine. Relative to the prolonged elimination of phormogen, it is found to be frequent in all forms of nephritis, but is also observed in other affections in which the kidneys have not been implicated.

**Central Neuron Endings.**—Semi Meyer (*Archiv für mikroskopische Anatomie*, July, 1899) contributes a careful study on the manner of nerve termination in the central nervous system. He believes that the old Gerlach reticulum has some place in modern histology, with modifications. In the light of recent work of Golgi and Cajal with the intra-vitam methylene blue method, supplemented by some observations here made, he holds that the ending of the nerve fibres about nerve cells is more complicated than was formerly held, and that it is probable that a nerve fibre comes in contact with the body of a nerve cell and spreads about it and completely encompasses it about with fine processes. He states that the neuron theory, in the Waldeyer sense, still holds, and the continuity of fibrils, as claimed by Apathy and Bethe, is not yet by any means proven.

**Convulsions in Infancy.**—After a consideration of the frequency, etiology, pathology, and treatment of convulsions in infancy, Gossage and Coutts (*British Medical Journal*, August 19, 1899) submit the following conclusions: The frequency of convulsions in infants has been vastly overrated. The immediate danger of a fit has been overrated, while the danger as regards future neurotic manifestations has been underestimated. Predisposing causes are of much more importance than the exciting causes; slighter exciting causes will not produce convulsions except in predisposed infants. In the attack the clothing should be loosened and the child laid on its back, with the head slightly raised. Inhalations of chloroform or of amyl nitrite may be practised, chloral and bromide injected into the bowel or a small dose of morphine beneath the skin. Subsequently bromides or borax should be employed systematically.

**The Relation of Hæmochromatosis to Bronzed Diabetes.**—Opie (*Journal of Experimental Medicine*, vol. iv., Nos. 3 and 4) reports a case of hæmochromatosis, from a study of which, in conjunction with an analysis of the literature, he arrives at the conclusion that hæmachromatosis is a distinct morbid entity, characterized by widespread deposition of an iron-containing pigment in certain cells, and an associated formation of iron-free pigments in a variety of localities in which pigment is found in moderate amounts under physiological conditions. With the pigment accumulation there occur degeneration and death of the containing cells, and consequent interstitial inflammation, notably of the liver and the pancreas, which become the seat of inflammatory changes, accompanied by hypertrophy of the organ. When chronic interstitial pancreatitis has reached a certain grade of intensity diabetes ensues and is the terminal event in the disease.

**The Morbid Anatomy of Tuberculosis in Childhood.**—As the result of observations made in two hundred and sixty-nine cases of tuberculosis in children, Still (*British Medical Journal*, August 19, 1899) concludes that the commonest channel of infection with tuberculosis in children is through the lungs. Infection through the intestine is less common in infancy than in later childhood. Milk, therefore, is not the usual source of tuberculosis in infancy, perhaps owing to the precautions taken in boiling, sterilizing, etc. Inhalation is much the commonest mode of infection in the tuberculosis of childhood, and especially in infancy. The overcrowding of the poorer population in the large towns is probably responsible for much of the tuberculosis of childhood, and prophylaxis must be directed to the prevention of this overcrowding, the improvement of ventilation, and the inculcation of the extreme importance of fresh air during the earliest years of life.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 21, 1899.

## THE TREATMENT OF TETANUS BY INJECTIONS OF CARBOLIC ACID.

AN article upon the above subject appeared in the New York *Medical Journal* of September 9th, contributed by Dr. Flavel Woods, of Philadelphia. A case is cited in which, by means of large doses of carbolic acid administered hypodermically, a satisfactory recovery from tetanus was made, and Dr. Woods is of the opinion that carbolic acid used in this manner is a far more reliable curative remedy than any serum at present in use. However, many eminent scientific men are of one mind with Dr. Woods on this point, and testimony as to the efficacy of carbolic acid has been forthcoming from several different quarters for a considerable time. The treatment, in fact, is generally known as that of Baccelli, he having been the first to advertise to the world its excellent results. In the article on tetanus by Babes, in the seventeenth volume of the "Twentieth Century Practice of Medicine," that distinguished authority speaks in very high terms of the injection of carbolic acid as a remedial agent in tetanus, and describes the history of its first use and of his own experience in regard to its beneficial properties as follows: "Injections of carbolic acid were first recommended by Baccelli, on the strength of a cure obtained in a very grave case of tetanus. . . . Through the marked success of experiments on animals suffering from tetanus by carbolic acid, I was induced to try Baccelli's treatment, which, according to Italian observers, at first furnished good results, but is becoming obsolete, probably on account of the modern specific treatment. I am nevertheless constrained to mention it, as it has given me such good results. We will see that the statistics of the antitoxin treatment do not show any better results. As a result of my experience, I feel justified in urgently advising the injection of a carbolic-acid solution in all cases in which the tetanus antitoxin cannot be obtained."

This is the method employed by Babes: A half-per-cent. solution of carbolic acid is injected along the spinal column beginning at the neck, in doses of 5–10 gm. (℥ i.–iiss.) every two hours.

In the MEDICAL RECORD of September 17, 1898, is published an extract from the *Accademia Medica* of Rome, telling of the mode in which Ascoli carried out Baccelli's treatment. Ascoli injected subcutaneously 0.03–0.04 gm. of carbolic acid in the form of a two- to three-per-cent. solution, so that the patient received 0.35 gm. per day.

Comparing this treatment with that by serum injections, the *Accademia* publishes these statistics:

Baccelli's treatment, 1 death in 30 cases; Tizzoni's serum, 8 deaths in 40 cases; Behring's serum No. 1, 4 deaths in 11 cases; Behring's serum No. 2, 2 deaths in 9 cases. Lieut.-Col. W. G. H. Henderson reports in the London *Lancet* of June 3, 1899, that he has treated in India both human beings and horses with carbolic acid with marked success. Of twenty patients treated with 2 ♏ of carbolic acid in 20 ♏ of water three times a day seven recovered. Kitasato has demonstrated that carbolic acid acts as an anæsthetic, then as an antiseptic, and as an antidote to the toxin of tetanus. Dr. Woods recommends the use of carbolic acid in large and heroic doses, and argues from the recovery of the case under his care that it is effective only when administered thus, premising—and probably correctly—that if given boldly and as early as possible, so that the system may be quickly and completely saturated, its antiseptic properties will be manifest in the blood. Nevertheless this point will require further and more decided confirmation before it can be accepted as proven, especially, too, in face of the excellent results referred to above, and which were effected in a number of cases by the use of comparatively small doses of weak carbolic-acid solution. It is well that attention has been again called to a remedy which has in the past given such good results in the treatment of tetanus, but the merits of which appear to have been disregarded in the prevailing craze for serum therapy.

## GLYCERINIZED VACCINE LYMPH.

THE prevalence of smallpox of late in various portions of this country, though greatly to be deplored, has at least afforded excellent opportunities of testing the merits of glycerinized vaccine. In Great Britain opinions are unanimous as to its superiority over any other kind of lymph, and this view would seem to be shared by those physicians who have used this new mode of preparing vaccine in America. Dr. Albert Barnes, of Philadelphia, has thoroughly investigated the matter by means of statistics by letter and by personal inquiry, and the result has been that the testimony in favor of glycerinized vaccine was convincing. In Baltimore conservative estimate places the number of successful takes as ninety-five per cent. in primary cases. In Minneapolis there was a proportion of ninety-five per cent. successful takes in primary cases, and seventy-five per cent. in secondary cases. Reports of a like nature come from every portion of the country. Dr. Barnes draws the following conclusions from his investigations:

This investigation proves conclusively that the recommendation of the United States Marine-Hospital service, that "glycerinized vaccine only should be employed," is well substantiated by experience, because:

(1) Properly prepared glycerinized vaccine is pure

and free from staphylococci, streptococci, and other pathogenic organisms which are invariably found on vaccine points.

(2) Glycerinized vaccine affords absolute protection against smallpox; vaccine points are uncertain in this regard.

(3) Vaccination with the glycerinized products does not cause excessive inflammation of the vaccinated area. Cellulitis and inflammation of the lymph vessels and glands, amounting at times to abscess formation, is a not infrequent sequence of the use of vaccine points.

(4) Vaccine points are apt to lead to a false sense of security, inasmuch as they induce a local staphylococcic or streptococcic infection which is entirely distinct from true vaccination. Such a result is not protective against smallpox.

(5) A high estimate of successful takes from vaccine points is by these and numerous other reports shown to be not over sixty per cent. in primary cases and a much lower percentage in secondary cases.

(6) Glycerinized vaccine has been officially adopted by the governments and health authorities of the United States, Great Britain, Germany, France, Russia, and Belgium. It should be universally adopted in private practice.

## DISCUSSION OF THE PLAGUE IN BRITISH LAY JOURNALS.

The British journals, both medical and lay, are naturally devoting a considerable portion of their space to a consideration of the plague, and are eagerly debating the possibility of its gaining an entrance into Great Britain. As may be well imagined, agreement on this point is by no means unanimous. Some altogether pooh-pooh the idea as a fantasy of the wildest nature, and aver that even if a case or two is brought into the country, there is no more likelihood of its becoming domesticated than of a prairie fire occurring in the early spring. On the other hand, there are those who contend there is no accounting for the vagaries of the plague, and assert that if it once made a lodgment in the poor districts of some of the large cities it would find a congenial home. One of the most thoughtful papers on the plague yet published was that read by Professor W. J. Simpson, at the annual Congress of the British Sanitary Institute at Southampton. Professor Simpson, although not a pessimist, does not regard the position of Great Britain in reference to the plague as absolutely safe, and thinks it will not be advisable for the inhabitants of the United Kingdom to "live in a fool's paradise." He says: "Since its advent plague had caused in India over two hundred and fifty thousand deaths, the worst feature being its annual recurrence. Poona was but recently in the throes of its third epidemic, over one hundred and fifty dying per day. If a similar mortality prevailed in London the metropolis would lose over ten thousand persons a day. The mortality in Poona was all the more serious, as from a personal inspection of the town he could state that, if inefficient drainage be excepted, which allowed of waterlogging of the soil, it was no worse as regarded sanitation and overcrowding than hundreds of towns of similar size in Europe, and was certainly in a much better condition than many. The reappearance of plague in Egypt after fifty years, with its extension into Portugal, was a matter of profound interest, because it indicated that this plague from China partook rather of the nature of a pandemic than an epidemic, and possessed that which other plague epidemics for nearly the last two hundred years had lacked, namely, the quality of diffusiveness which defied the precautions even as revised by the Venice conference and hitherto adopted against its progress." We are of the opinion, as has been stated in former numbers of the Medical Record, that the plague has but little chance of appearing in epidemic form in Great Britain, but the truth must be confessed that the poorer sections of many of the large towns—for example, the Whitechapel and Bethnal Green portions of the East End of London—with their narrow, dirty, and overcrowded streets, might provide a suitable condition for the propagation and dissemination of the disease. The bacillic origin of plague is now recognized as settled. The bacillus is able to live and multiply in dirt outside the human body, and can, after being cast out of those attacked by the disease, exist for periods of varying length in dirt, and this fact undoubtedly partly explains why it is that the dwellers in uncleanly localities are more liable to plague infection than persons of the better class.

Plenty of ventilation and of fresh air will probably go further toward checking a plague epidemic than any other means. In the case of Great Britain, however, it is certain that stringent measures will be taken to prevent the disease from even entering the country.

## SEMI-TEMPERANCE SALOONS IN GREAT BRITAIN.

The English papers record the opening of a new saloon (public house in England) at Grayshot in Hampshire. In itself this is not so unusual an event as to justify notice even in the last week of August. What gives it interest is the exceptional character of the house. The "Fox and Pelican" is a fresh experiment on lines originally suggested by the Bishop of Chester, and already in operation on a small scale under the control of an association of which he is president. The object of the association is to turn saloons into refreshment rooms to push the sale of food and non-intoxicating drinks, in comparison with that of alcohol, and to exact from the customers a stricter observance of order and decency. The association and its kindred houses mean to wage war with drunkenness and rowdyism, while giving decent people, whether workers or wayfarers, all that they can get at a saloon and something more besides. The way in which they mainly hope to secure these ends is by enlisting the interest of the manager on their side. He is charged for alcoholic drink the full retail price, and on non-alcoholic beverages he is charged such a rate as to enable him to make a profit of twenty per cent. He has

a positive inducement, therefore, to push the consumption of the latter, and none at all to push the consumption of the former. Add to this that he is paid a good salary, and is constantly urged by his employers to be very strict in keeping order and in refusing to serve drunken people, and we have the main particulars of the scheme. This plan reminds us somewhat of tea saloons recently established in New York; the only difference is that in the New York tea saloons no alcoholic beverage is sold at all. But at any rate the object is the same, and it goes to show that the tendency of the times is, in both Great Britain and the United States, to restrain as much as possible the drinking-habits of the people.

## News of the Week.

**Overcrowding in a Hospital.**—So extensive is the number of inmates in the Pennsylvania State Hospital for the Insane at Norristown that of the eleven hundred and three male patients six hundred and eight are compelled to sleep in the corridors and on mattresses on the floors.

**Tuberculosis in Alaska.**—The captain of a steam whaler recently arrived in San Francisco reports that a disease resembling acute tuberculosis is prevailing among the natives in many parts of Alaska. During his stay at Point Barrow, from August 14th to September 7th, there were nineteen deaths, and during a few hours that the ship was at Cape Bathurst three of the Indians died.

**"Contract Doctors" in the British Army.**—Owing to the folly of Her Majesty's "military advisers," the medical service of the British army is inadequately supplied, and the authorities have been obliged to employ a number of civil practitioners. They are not paid a fixed salary, but receive compensation at the rate of four shillings per annum for every person in the command to which they may be assigned. It is said there is no dearth of applicants for these poorly paid jobs.

**A Large Drug Store.**—The pharmacy of K. I. Ferrin, at Moscow, Russia, is thought to be the largest in the world. Two hundred and ninety-three men are employed in the wholesale and retail departments. As many as twelve hundred prescriptions are put up in one day. If poisonous drugs are used in putting up a prescription, the checking of weights is done by a weigher specially employed for that purpose.—*The Medical Age.*

**The International Conference on Syphilis,** which was held at Brussels in September, accomplished little or nothing in the way of mitigating the evil of this disease, though it was prolific of resolutions. Those resolutions were (1) to urge upon governments the absolute suppression of juvenile prostitution; (2) to take steps for the organization of an international society of sanitary and moral prophylaxis; (3) to urge upon university authorities the establishment of obligatory courses in venereal diseases; (4) to provide for the protection and moral training of orphans; (5) to secure the execution of all laws looking to the punishment of men or women who live upon money earned by others by prostitution; (6) to secure the appointment of a commission in each country to collect statistics regarding the frequency of venereal disease, institutions for the treatment of these diseases, and measures best adapted to the repression of venereal diseases; (7) to secure the general dissemination of knowledge regarding the danger to health of syphilis and other venereal diseases, and (8) to secure a uniform basis for the arrangement of statistics of venereal diseases in the various countries of the world.

**Relics of Volta.**—Among the few relics of Volta saved from the burning down of the Como electrical exhibition are the original Voltaic pile, about twenty manuscripts and some autograph letters, a few books from his library, and about fifty drawings, paintings, and medals.

**The Smoke Nuisance.**—Two men were fined this week in the court of special sessions for burning soft coal, the charge having been brought by the board of health. This is a most encouraging beginning. There are several chimneys very near the building of the Health Department which pour forth black smoke daily, and we would commend the persons responsible for this to the kind offices of the health officials. One of the chimneys is connected with a power house, another with a newly built club house. Here is an excellent opportunity for the chastisement of sinners in high places.

**Typhoid Fever at Newport.**—The newspapers report the occurrence of a mild epidemic of typhoid fever among the naval apprentices at the training-station in Newport. Up to October 11th, there were sixteen cases. The patients are in the naval hospital on Coasters' Harbor Island. There are about three hundred and fifty apprentices at present at the station. In the city of Newport there are only six or eight cases of typhoid fever. Nine years ago there was an outbreak of the disease at the training-station and several deaths occurred.

**The Plague.**—There has been a slight recrudescence of the plague in Oporto, some eight or ten new cases being reported daily. The disease has appeared in North China and on the Ladrones Islands. A steamer arrived at Plymouth, England, on October 14th, from Bombay with one of the crew ill with the plague. The disease developed only a few days before the arrival of the vessel at Plymouth. It is announced that Lord Curzon, Viceroy of India, and his staff will shortly visit the districts where the people are suffering from famine and the bubonic plague. Before leaving Bombay they will be inoculated with the anti-plague serum.

**Fire at the Loomis Sanatorium.**—The administration building of the Loomis Sanatorium in Liberty, Sullivan County, was entirely destroyed by fire at noon on Saturday last. Very few patients lived in that building, and they were all out at the time the fire

broke out. Very little of the furniture and other contents of the building was saved. This building, known as the Loomis Memorial, was a stone structure, the gift of Mr. J. P. Morgan, and was built some years ago. In addition to the administration building there are nine cottages and a casino, none of which was injured. The house that was burned was used as a residence for the physicians, and in it were also the dispensary and dining-hall in addition to the administration offices.

**Typhoid Fever from the Thousand Islands.**—The death from typhoid fever of several persons, and the illness of a number of others who summered at one of the large hotels in the Thousand Islands, have been reported to the State board of health from Syracuse, Auburn, and other places. An investigation will be made of the sanitary condition of the hotel.

**Diphtheria in Newark.**—The board of education and the board of health of Newark are at loggerheads regarding diphtheria in two of the schools. It is said that the schools are in an insanitary condition, and the health officers threaten to close them unless the board of education makes the necessary repairs and alterations. There have been eleven cases of diphtheria in one of the schools and fifteen in the other.

**Three Aged Physicians.**—Drs. v. Hochberger, of Carlsbad, and Nieberding, of Vasel, near Oldenburg, recently celebrated the completion of their seventieth year as practising physicians. The first is ninety-six years old and the second ninety-four. Dr. Kohlschmitt, of Oldenburg, is, however, the dean of German medical men, having begun practice over seventy-one years ago, but he is younger than either of the other two, being but ninety-three years old.

**Typhus Fever on Shipboard.**—The German steamship *Aragonia*, from Antwerp, which reached Philadelphia on October 11th, brought two passengers suffering from typhus fever, and the body of one dead from the same disease. The latter was a Russian, who embarked at Libau, where typhus is epidemic. Through the neglect of some one the facts were not made known to the authorities until after the passengers had been landed. The names and residences of six of the passengers who reside in New York City have been given to the board of health, and the health officers have taken the necessary precautions to prevent the spread of the disease in this city.

**Public Funds for Private Charities.**—At a recent meeting of the board of estimate and apportionment the plans of Comptroller Coler for a more equitable distribution of the funds of the city to charitable institutions came up for consideration. These plans include the making of all donations from the budget to the exclusion of the excise and theatrical funds; the payment of a uniform rate of $2 a week for the maintenance of children over two years of age, and thirty-eight cents a day for infants; the abolition of lump-sum payments to hospitals, and the substitution of a uniform rate of $1 a day for surgical cases and seventy cents a day for medical cases; the limitation of the amount paid by the city to be fifty per cent. of the amount received by institutions from private sources; a gradual reduction of appropriations in support of homes for the aged; the discontinuance of out-door relief, and the placing of all institutions on the same footing as regards the receiving of pecuniary aid from the city.

**Typhoid Fever at the Virginia Military Institute.**—Owing to the prevalence of typhoid fever at the Virginia Military Institute in Lexington, the superintendent has furloughed the entire corps of cadets for thirty days. The corps numbers two hundred and fifty young men from all parts of the United States.

**Gift of a Hospital Ship to Great Britain.**—The Atlantic Transport Company, which gave the United States government a ship for hospital purposes during the war with Spain, has now done Great Britain a similar service in offering the *Maine* free to the government. The Admiralty has accepted the vessel.

**The Yellow Fever** at Key West is gradually dying out, apparently because the number of susceptible individuals is being reduced. There are ten or twelve new cases daily, and the mortality is slight. Santiago threatens to quarantine against Key West and Havana because of the arrival at that port of several steamers with yellow fever from those places. There has been no case of the disease in the province of Santiago since the beginning of this month. A dispatch from Madrid says that the *Gaceta Oficial* of that city has published an order of quarantine against all vessels arriving from New Orleans, as a precaution against yellow fever.

**Two States at Law Regarding Quarantine.**—The attorney-general of Louisiana is about to institute proceedings before the supreme court of the United States at Washington praying for an injunction in the name of the State of Louisiana against the State of Texas, to restrain the latter from interfering with the commerce of Louisiana by her quarantine restrictions imposed on account of yellow fever in New Orleans. The suit was brought at the demand of the merchants of New Orleans, who complain that Texas has kept in operation an embargo against Louisiana since May that is unreasonable and unjust. There have been several of these quarantine wars between the Southern States during the last three years, notably between Alabama and Mississippi, and between Louisiana and Texas, but this is the first time that the quarrel has been carried into the Federal courts.

**The Clinical Society of Maryland.**—At the first meeting of the season of the Clinical Society of Maryland, held at the hall of the Medical and Chirurgical Faculty on Friday, October 6th, the following officers were elected for the ensuing year: *President*, Dr. James M. Craighill; *Vice President*, Dr. W. J. Todd; *Recording Secretary*, Dr. H. O. Reik; *Corresponding Secretary*, Dr. Nathan Herman; *Treasurer*, Dr. N. R. Gorter; *New Member of Finance Committee*, Dr. J. W. Lord; *Executive Committee*, Drs. Henry B Jacobs, W. S. Gardner, and J. R. Abercrombie.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 13, 1899. October 6th.—Medical Inspector J. A. Hawke promoted to medical director. Surgeon P. A. Lovering ordered to the Mare Island navy yard. Surgeon D. O. Lewis detached from the Mare Island navy yard and ordered to the *Iowa*. Surgeon M. H. Simons detached from the *Iowa* and ordered to Washington, D. C., October 23d, for examination for promotion, and then home to wait orders. October 9th.—Surgeon L. W. Atlee detached from the *Solace* and resignation accepted. Passed Assistant Surgeon C. P. Bagg detached from the *Pensacola* and ordered to the *Solace*. Passed Assistant Surgeon J. E. Page ordered to the *Pensacola*. Assistant Surgeon W. M. Wheeler detached from the *Solace* and ordered home to wait orders. October 12th.—Medical Inspector C. A. Siegfried detached from the torpedo station, Newport, R. I., October 17th, and ordered to continue in charge of the naval hospital, Coasters' Harbor Island, R. I. Surgeon J. M. Steele ordered to duty at the torpedo station, Newport, R. I., October 17th.

**Insects in Relation to Foot-and-Mouth Disease.**—At the recent congress of veterinary surgeons at Baden-Baden, Dr. Hecker, of Halle, maintained that foot-and-mouth disease can be carried from the sick to healthy animals by flies and other insects.

**The New Brunswick Medical Society.**—At the annual meeting of this society, held at Fredericton, N. B., July 19, 1899, the following officers were elected for the ensuing year: *President*, Dr. William Bayard, of St. John; *First Vice-President*, Dr. R. L. Botsford, of Moncton; *Second Vice-President*, Dr. T. F. Sprague, of Woodstock; *Treasurer*, Dr. Foster McFarland, of St. John; *Corresponding Secretary*, Dr. B. M. Mullins, of St. Mary's; *Recording Secretary*, Dr. W. Leonard Ellis, of St. John. The next meeting will be held in St. John, N. B., in the summer of 1900. The meeting of the Maritime Medical Society will be held at the same time and place.

**A Young Boer Surgeon.**—Paul Hendrick Krüger, a nephew of President Krüger, is a recent graduate in medicine of the University of Edinburgh, where he won the Syme surgical scholarship.

**American Public Health Association.**—The twenty-seventh annual meeting will be held at Minneapolis, Minn., Tuesday, Wednesday, Thursday, and Friday, October 31st, November 1st, 2d, and 3d.

**A Physician Heavily Mulcted.**—A verdict for $13,092 was given on October 14th at Reading, Pa., against Dr. John Edge, as damages for the result of a surgical operation upon a woman; $8,092 to the patient herself, and $5,000 to the husband for the loss of his wife's services.

**American Electro-Therapeutic Association.**—The ninth annual meeting of the American Electro-Therapeutic Association was held in Washington, D. C., at Willard's Hotel, on September 19, 20, and 21, 1899. The convention was very successful in point of attendance and interest and a number of papers of scientific value and importance to the medical profession were read and discussed. The programme included thirty-six papers and the reports of seven standing committees on scientific questions relating to the medical application of the electrical current with the best electrical apparatus extant. The proceedings of the convention will be found in their annual Transactions, to be published at an early date. The officers elected for the tenth year are: *President*, Walter H. White, M.D., Boston, Mass.; *First Vice-President*, D. Percy Hickling, M.D., Washington, D. C.; *Second Vice-President*, Charles O. Files, M.D., Portland, Me.; *Treasurer*, Richard J. Nunn, M.D., Savannah, Ga.; *Secretary*, George E. Bill, M.D., Harrisburg, Pa. The next annual meeting will be held in New York City on September 25, 26, and 27, 1900.

**A Reception to Drs. Keen, Osler, and Fitz.**—A reception will be given by the New York State Medical Association to Drs. Keen, of Philadelphia, Osler, of Baltimore, and Fitz, of Boston, on Wednesday evening, October 24th, at the Academy of Medicine.

**Clinical Lectures on Diseases of the Skin.**—Dr. L. D. Bulkley will, on Wednesday, November 1st, begin his second course of clinical lectures on diseases of the skin in the out-patient hall of the Skin and Cancer Hospital, Second Avenue and Nineteenth Street. The lectures, which are free to the medical profession, will be given each Wednesday at 4:15 o'clock.

**Obituary Notes.**—Dr. John H. Cochran, a prominent physician of Harford County, Maryland, died on October 10th, at the age of sixty-six years. He graduated at the University of Maryland in 1860, and at the time of his death was surgeon for the Philadelphia, Wilmington and Baltimore Railroad. Dr. Cochran was mayor of Havre-de-Grace in 1892.—Dr. William Ralph McAdam, Assistant Surgeon Marine Hospital service, died of yellow fever at Key West, Fla., on October 12th. He was born in Mercer, Pa., February 23, 1870. His father was a chaplain in the United States army. Dr. McAdam was a graduate in arts of the Iowa Wesleyan University and in medicine of Jefferson Medical College of Philadelphia in 1897. He was appointed an assistant surgeon in the Marine Hospital Corps August 3, 1898, and was assigned to command the Marine Hospital at Key West, February 25, 1899.—Dr. James Campbell, of Hartford, Conn., died on October 17th at the age of fifty-one years. He was a graduate of the Medical Department of the University of Vermont in the class of 1871. He was for several years professor of obstetrics and gynæcology at the Yale Medical School, and last year was appointed lecturer on life insurance. He was also president of the Hartford board of health.—Dr. David C. Card, of Willimantic, Conn., died at his home there on October 16th, after an illness of several weeks, aged seventy-four years. He was a graduate of the New York University Medical College in the class of 1850, and had practised in Willimantic for thirty years. He is survived by a widow and one son.

# Society Reports.

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Proceedings of the Twenty-fifth Annual Meeting, Held in Chicago, October 3, 4, 5, and 6, 1899.*

### MEDICAL SECTION.

(Continued from page 571.)

Dr. Charles T. McClintock, of Detroit, Mich., presided. He read a paper on "Enzymes and Immunity," in which he deduced the fact that the enzymes are unorganized ferments and are directly responsible for immunity.

**Recent Physio-Chemical Researches as to the Physiological Action of Lecithin and Other Phosphorus Compounds.**—Dr. L. H. Warner, of Brooklyn, read a paper with this title. He said that by means of numerous experiments he had demonstrated that the organic phosphorus compounds were tissue builders, performing an important part in the tissue metabolism, especially in the causation of subsequent changes in the animal cells and controlling the formation of tissue. No abnormal conditions resulted if the food contained a sufficient amount of lecithin, phospho-carnic acid, and other phosphorus compounds. The most beneficial results followed their use, and they therefore were indicated in the treatment of all wasting diseases. Lecithin was always found in mother's milk, in lesser quantities in cow's milk, and rarely ever in the artificial foods for infants; hence their inefficiency. Organic phosphates, lecithin, and phospho-carnic acid were necessary in order to maintain perfect health. These salts were derived from any of the body tissues, and especially from beef when they were to be added to any artificial foods.

**Quinine in Some Phases of Malaria.**—This paper was by Dr. William B. Burns, of Deckerville, Ark. The author was of the opinion that malarial and typhoid fevers were never found present in any one individual at the same time; furthermore, he made the positive statement that any fever which did not yield to the proper administration of quinine was not malarial, and if typhoid had been excluded by diagnosis, the condition was due to an auto-intoxication. He cited one case of malaria developing marked purpura hemorrhagica and hæmoglobinuria, which responded readily to quinine and tincture of perchloride of iron. Another case simulating pneumonia, with the hæmatozoön present in the blood, however, also yielded to alterative treatment and quinine. Symptoms of abnormal renal function, such as albuminuria and hæmoglobinuria, so often found in malarial cachexia, completely disappeared after the use of quinine. He had not been able to demonstrate the malarial organism in any stage of development in the mosquito, although he found an abundance of pigment, but not of the malarial variety. He administered quinine in doses of from gr. iii. to v. every three hours, for from twenty-four to forty-eight hours, beginning at the commencement of the decline of the fever, as the plasmodium at this time was less capable of resistance and phagocytosis was at its best. In malarial cachexia quinine should be administered in doses of from gr. iii. to v. three times daily, preferably on a full stomach, in order to avoid tinnitus and nervousness. Relapses might be prevented by doses of gr. x. on the fifth, sixth, and seventh days at bedtime.

Dr. L. H. Warner, of Brooklyn, remarked that Dr. Burns made a rather bold statement by saying that any fever which did not yield to quinine was not malarial. Quinine was a poison only to the full-grown germ, but did not kill the spore; consequently, if it was given even for thirty or forty days, it killed the germ, but the spore escaped, and it might for years lie dormant until a favorable moment arrived for it to develop and produce a new paroxysm. The amount of chlorides in the blood constituents and in the blood plasma exceeded the total amount of sulphates and chlorides. The parasite attacked the red blood corpuscle and destroyed it. Now, if there was a superabundance of chlorides, the corpuscles were not destroyed; therefore we must use chlorine, and it would destroy not only the organism but its spores as well. In cases coming from the hot-beds of malaria the patients were dosed with quinine up to gr. xl. at a time, and still the parasite grew, but as soon as the patients were put under treatment with quinine simplex plus chlorine, or chlorine plain, there was neither organism nor spore left. He thought that chlorine was one of the most important factors in the treatment of malaria, and it might be used alone or with quinine plain, but not with the sulphate.

Dr. T. B. Greenly, of Meadow Lawn, Ky., mentioned that in the good old times they did not give quinine until the fever was modified. They bled, purged, and salivated, but gave no quinine. In many cases the patients were far gone when the time arrived for the administration of quinine. This finally forced him to the conclusion that if quinine was good for fever, it was good while fever was present as well as when it was not. After regulating the bowels with rhubarb, he administered the quinine. With this method he had lost only one case in a period of over six months, and that was a case of the congestive variety. In every instance he effectually combated malaria by the administration of quinine.

Dr. Warner mentioned having had a case of undoubted typho-malarial fever in which were found both the malarial organism in the quartan form and the typhoid bacillus. After the patient's death the question arose between Dr. Warner and Dr. Sternberg as to how to make out the death certificate, as both germs had been present. Under the existing circumstances during the last war, and also during the Civil War, there were undoubtedly cases in which there was a combination of malaria and typhoid, and the term "typho-malarial fever" would be the proper one to use, as both germs were found present.

**The Successful Treatment of Graves' Disease as an Auto-Intoxication.**—This paper was read by Dr. Charles L. Minor, of Asheville, N. C. After reviewing the various theories of the etiology of Graves' disease, and especially the thyrogenic theory, he reported two cases which he treated on the supposition that the disease was dependent on an intestinal auto-intoxication. A positive cure resulted in one of them. He based his belief on the constant presence in excess of ptomaines in the intestine, and their violent effects on the system and especially on the gastro-intestinal tract. The treatment consisted of a strictly regulated diet, in which the starches, sugars, and table dainties were cut down to a minimum or entirely eliminated, with rest at first, followed by carefuliy graded exercises, and good hygiene. Medication consisted of the administration of the lactate or albuminate of iron, anti-ferments at meal time, with an occasional mercurial purge and intestinal lavage, to which the author had given the unique name of "liver wash." Large quantities of water were used at a temperature of 102° F., and were retained one-half hour. This increased the liver activity, and all the emunctories were stimulated, thus effectually eliminating all toxins. Lavage was continued at intervals for over a year, and in one case was followed by an apparently complete restoration to health, except for a slight, almost imperceptible, prominence of the thyroid. The second case, while

still presenting objective symptoms, was entirely free from any subjective symptoms.

Dr. George W. Webster, of Chicago, remarked that the treatment at present was based on an increased activity of the thyroid gland with altered secretion, which acted on an unusually nervous system. He referred to a reported case which had been treated by injections of bile as high as gr. c. a day on the supposition that bile acted as an antiseptic. A cure resulted. At the same time he called attention to the fact that nearly fifty per cent. of these patients get well without any treatment whatever; others by surgical means, and still others by means of various medicinal agents. This did not furnish any clew, however, as to the real cause for the increase and perversion of the thyroid activity. Dr. Minor's paper established a primary cause in at least two cases, and his paper must therefore be considered as an important contribution to the study of Graves' disease.

Dr. Hugh T. Patrick, of Chicago, did not agree with the essayist in that the poisons generated in the intestinal tract, and which were absorbed from it, played any part in the causation of Graves' disease. These noxious substances from the bowel were etiological factors only in so far as were alcohol, syphilis, over-exertion, etc., in any other disease, and to draw conclusions from only two cases was a practice which was not to be recommended in medical research. Proper care must be given to the intestinal tract in any disease, and the numerous investigators on this subject had as yet not been able to adduce anything which might be considered as a positive proof that auto-intoxication of the intestinal tract could have any bearing as a cause of Graves' disease. After briefly referring to the various methods of treatment, the speaker mentioned one case which had been subjected to every known treatment without avail, and the patient was finally taken home in a very serious condition. All treatment was discontinued, and inside of three months the patient had perfectly recovered.

Dr. Minor, in closing, stated that he did not intend to use these two cases as an argument for all cases of Graves' disease, but intestinal auto-intoxication he believed to be one of the primary causes of the affection, and it certainly was worth while to give this condition of the bowel proper attention, as it had been almost entirely overlooked by previous investigators, who laid most stress on shock, fright, dietetics, etc.

**The Treatment of Pulmonary Tuberculosis by the Inhalation of Antiseptic Nebulæ.**—Dr. Homer M. Thomas, of Chicago, read a paper with this title. Nebulization was supportive only, but was of great value as a secondary factor in the treatment of tuberculosis. It aided in establishing a barrier around the tuberculous area by stimulating cellular structure to resist the germs and their toxins. The beneficial effects of nebulization were: (1) to control the cough; (2) relief of dyspnœa; (3) intimate contact of the nebulæ with much of the respiratory cavity; (4) inhibition to the extension of the tuberculous foci. The cough was best relieved by tincture of stillingia and beechwood creosote with a lavolin base. For dyspnœa he gave expectorant combinations with carbonate of ammonia, syrup of squills, and prunus virginiana, with lavolin for a base. Various other remedies were mentioned, and special attention was called to formalin in from four- to twenty-per-cent. solution, depending upon the patient's ability to stand a weak or strong solution. The nebulæ penetrated wherever the air did, and were by means of phagocytosis conveyed through the blood and lymphatics to the tuberculous overgrowth. While the nebulæ did not reach the encapsulated tuberculous area, they inhibited extension of the disease. The atmosphere of the room as well as the respiratory passages must be saturated with the medicament. Clinical experience having proven the value of vaporized medicaments in tuberculosis, further trial and investigation were justified.

Dr. T. B. Greenly, of Meadow Lawn, Ky., stated that he had for some time past been using a mixture of formaldehyde and ammonia with the most salutary results. The ammonia enabled the patient to bear more of the formaldehyde vapor, and the system thus became more rapidly immune to the toxins of the tubercle bacillus. He had lately been using urotropin, a combination of formaldehyde and ammonia, and inside of ten to fifteen days it thoroughly disinfected the sputum, and it was absolutely free from bacilli. This treatment, with the addition of tonics, increased the patient's appetite, the cavities healed more rapidly, and a speedy recovery resulted. Urotropin acted equally well in bone tuberculosis. He also used in phthisis iodine and theobromine with massage twice daily, so as to get the action of the iodine in the circulation without imposing on the stomach. Perfect satisfaction had followed this treatment in his experience of over one hundred cases of tuberculosis.

Dr. Charles L. Minor, of Asheville, called attention to the fact that a combination of formaldehyde and ammonia destroyed completely the action of the former, and therefore the good results which Dr. Greenly obtained could not have been due to the inhalation of formaldehyde. He expressed his gratification that Dr. Thomas regarded the inhalation of medicated vapors as an adjuvant only. In his experience patients who inhaled simply the air around them did as well as though medicated vapors had been used, and pure air had the advantage of producing no irritation whatever.

Dr. J. M. Patton, of Chicago, congratulated the essayist on the conservative view taken of the therapeutic effects of inhalation of medicated vapors. Neither inhalation nor the injection of different oils into the respiratory tract had given any definite results so far as a cure was concerned, which really could not be expected in view of the existing pathological changes. Councilman had demonstrated a collateral zone of congestion around the tuberculous area, which contained no tubercle bacilli, but had sufficient circulation to admit of absorption and poisoning. These areas prevented anything from reaching the tuberculous area itself. The failure of serum therapy demonstrated the futility of reaching these areas through the circulation; nevertheless beneficial results followed the use of these measures, as they lessened the cough, diminished bronchial secretion, and improved the respiratory function. In chronic bronchitis great good followed the use of vaporization, as anything that would lessen bronchial secretion would correspondingly lessen the danger of secondary infection from the tuberculous areas. As to the possibility of considerable good arising from the absorption of the vapor through the bronchial membranes into the system, Dr. Thomas was illogical.

Dr. Thomas, in closing, expressed his gratification at hearing the good results which Dr. Greenly had had with formaldehyde and ammonia. Inhalation was advocated only as an adjuvant, the only value, if none other, being in the deep breathing which it excited and the psychical impulse created in the use of nebulæ, which was not the case when air was used. This effort at deep breathing was very much to be desired in the impaired respiration of tuberculosis. The author expressed the belief that "we were strong in medication, and weak in therapeutics."

**Do We Need to Think?**—This paper was read by Dr. William O'Neal Mendenhall, of Richmond, Ind. He presented a report of a peculiar case of hereditary nervous diarrhœa in a young man, indirectly caused by a fall of the mother producing a fracture of the coccyx. Treatment consisted of strychnine,

to act as a nerve tonic, and ergot to act on the circular muscle fibres of the bowel, with regulation of diet and hygiene. A complete recovery resulted.

**The Evils; Their Causes and the Remedy that will Edify Medicine in the United States.**—Dr. A. M. Osness read this paper. He said that the evils were held to be "mushroom schools," antagonistic pathies, overcrowding in the profession, lack of scientific spirit among medical teachers, undue ostentation, and unscrupulous intrigues in the profession. The causes of these evils were, first, paltry remuneration for professional services; second, the fallacy of a profitable notoriety. The author suggested as a remedy the regulation of schools and professorships; obligatory interneships of all who were graduated; conditioning that diplomas should be revocable for unprofessional conduct; charity hospitals to be under the supervision of medical men; the encouragement of strictly prescription pharmacies.

Dr. William F. Barclay, of Pittsburg, Pa., felt that there was an implied disparagement of the American physician. He was of the opinion that physicians in this country compared favorably with those educated abroad, and that our schools and colleges were equal to any and superior to many of the foreign schools. We had the advantage over the foreign physician in understanding thoroughly our own language, but that ought not to be offered as an excuse for any disparagement of American physicians and American institutions. Much that the essayist had said was worthy of appreciation, and especially his reference to charity work, as it was difficult to know just where charity ended and imposition began. The points about the dispensing pharmacists were well taken, but much had been done to lessen the demand for proprietary medicines by placing them in the general stores at the least rates. The question as to how to remedy all these evils was a very difficult one to solve, and would consume too much time.

Dr. E. M. Epstein, of Chicago, remarked that in his experience he had found that all American physicians are very well received in Europe. The only remedy for all the evils portrayed by the essayist in his estimation was to have representation in the Cabinet of the President of the United States, by a secretary who is to be appointed or elected irrespective of politics. Then physicians would have some one to speak for them and to look after their interests.

Dr. John Punton, of Kansas City, Mo., believed the remedy rested with the physicians themselves, who must enter politics and be willing to go to the legislature to demand the rights which were due the medical profession, and as long as this was not done they could not expect to be recognized by the government.

Dr. C. M. Skinner, of Hartland, Wis., speaking for the pharmacists, said that they had been forced by the doctors to resort to counter prescribing, as, in the majority of instances, the doctors used their own medicines and even went so far as to dispense hot-water bottles, syringes, etc.

Dr. C. J. Lewis, of Chicago, agreed with the essayist that it was impossible for a scientific investigator to be engaged in any commercial pursuit at the same time. Physicians certainly ought to have a supervising mind in the Cabinet at Washington, and only in this way could their many professional evils be remedied.

**Two Cases of Typhoid Fever with Unusual Complication in Very Young Children.**—This paper was read by Dr. E. B. Montgomery, of Quincy, Ill. The author reviewed the literature on typhoid fever occurring in infancy and childhood, and reported two cases. One, in an infant of nine months, presented symptoms simulating a tuberculous meningitis, recovery taking place on the twenty-third day. The second case developed a suppurative parotitis about the twenty-fifth day with aphasia. After surgical treatment of this condition recovery resulted on the forty-fourth day. A search revealed but three cases in which there was involvement of the submaxillaries. He also mentioned one unreported case which occurred in the practice of Dr. Rook, of Quincy.

Dr. J. O. Malsbury, of Peru, Ind., believed that typhoid fever in infants under six months was more common than was generally supposed, and that cases were often wrongly diagnosed, being termed "catarrhal fever." A very important diagnostic point was to determine the proximity of typhoid in the neighborhood, or whether it had existed in the family some months prior to the present case. This had occurred in his practice several times.

Dr. Archibald Church, of Chicago, believed that meningeal symptoms were very common in typhoid, but were taken too much as a matter of course, and little attention was paid to them. It had been proven by culture experiments that the typhoid bacillus or its product entered the cerebral cavity. A certain amount of cerebral disturbance was expected in every case of typhoid, and it was the symptoms which made the diagnosis between typhoid and meningitis a difficult one. In the case presented there was no doubt an invasion of the cranial contents, the same as occurred in the intestines and elsewhere. That recovery took place after a severe invasion was proven by noting the percentage of recoveries from typhoid with marked cerebral symptoms.

**Further Observations on the Treatment of the Abdominal Viscera through the Colon.**—Dr. Fenton B. Turck, of Chicago, read this paper. It was a very interesting one, and the author dwelt particularly on the importance of colonic lavage in the treatment of all diseased conditions of the bowel. He explained his method very fairly, illustrating it by a series of experimental reports.

Dr. William F. Barclay, of Pittsburg, expressed himself as being very much opposed to the indiscriminate injection of large quantities of water into the bowels. He was pleased to learn that Dr. Turck used only a small quantity of water, as large quantities had in his experience proved injurious. He especially condemned the use of syringes, as they destroyed the muscular tone of the bowel, and a constipation was set up which was almost irremediable. Cathartics, too, were unpleasant to use, but cathartic medication in conjunction with regulation of diet was to be recommended.

Dr. T. Wertz, of Evansville, Ind., saw no reason why the bowel should not give out the same as any other organ. Many persons were incapacitated for business on account of constipation, and from the constant use of cathartics their stomachs had become irritable, so that they were obliged to resort to water enemas. In cases in which there was a paralysis of the bowel or insufficient peristalsis, water enemas were the remedy. Many lives had been prolonged by the use of food enemas when the stomach was non-retentive and needed a rest.

Dr. C. J. Lewis, of Chicago, thought that there was a general agreement at the present time that the saprophytic bacteria in the intestinal tract were the cause largely of appendicitis. Colonic lavage facilitated diagnosis, as we needed only to unload the bowel of its accumulated bacterial infection in order to make possible more accurate palpation of the appendix and thus determine its condition of inflammation.

Dr. Thomas J. Schuell, of Parnell, Ia., for many years believed himself to be the originator of colonic lavage in the treatment of appendicitis. The usual idea was to unload the cæcum, but by using water at 110° F. it would not only unload the cæcum and colon, but it would at the same time excite the peristalsis of

the cæcum as well as the appendix. Many cases of appendicitis were due to impaction of the colon producing paralysis of the muscle fibres and the formation of a ball-valve action of the cæcum, and by means of a slight shock, such as jumping, the fecal matter was forced into the appendix, and bacterial decomposition set in, with inflammation, necrosis, and pus formation. Colonic flushings should be given every three or four hours for the first twenty-four to thirty-six hours, and after four or five flushings beneficial results were very apparent.

Dr. Turck, in conclusion, emphasized the value of using the colon as a means of treating the abdominal viscera. It was not the quantity of water so much as the temperature which procured the characteristic reaction. Hot water drew out the water from the intestines, and the originally injected quantity was thus increased. The temperature raised the body temperature two or three degrees, and like cold was a vasomotor stimulant. Fecal matter was a normal stimulant to peristalsis, and the same effect could be produced by artificial stimulants. This could be done by means of small quantities of water, and when it was desired to produce gymnastics of the bowel hot air was urged, and it acted on all the abdominal viscera at the same time as a stimulant.

**A Case of Complete Hernia of the Pregnant Uterus, in a Xpara.**—Dr. W. V. Anderson, of Toledo, Ohio, reported this case. After thirty-six hours' duration of labor examination revealed separation of the recti muscles with a complete uterine hernia, the fundus reaching to the knees. The uterus was freely movable and the os was dilated. Contractions were good but ineffectual, owing to the position of the uterus; expulsion was interfered with by constriction of the cervix. Under anæsthesia the uterus was returned, the forceps applied, and a living baby was delivered without any difficulty.

**Pathogenesis of Functional Nerve Diseases and Its Prophylactic Indications.**—This paper was read by Dr. John Punton, of Kansas City, Mo. In the pathogenesis of nervous diseases heredity stood foremost, as the results of injurious living on the part of the parents were often transmitted to the offspring. Pathological changes were produced in the blood, which acted on the nervous system in such a manner as to cause actual disease. In certain nervous diseases the red blood corpuscles disintegrated and the plaques were much multiplied. Good diet and tonics tending to improve the system and the condition of the blood speedily restored health. In this connection the study of sociology ought to claim earnest attention, as it was a most important factor in the causation of nervous diseases.

Dr. Philip Zenner, of Cincinnati, thought that much could be done to lessen the tendency to the development of diseases of the nervous system when hereditary influences existed, by taking proper care of the child from the time of birth. He believed that the essayist was too optimistic as to the condition of the blood being an etiological factor, although improvement of the system was essential and productive of good results. The mental condition of the patient must also be improved by suggestion.

Dr. Daniel R. Brower, of Chicago, made it a routine practice to ascertain the exact condition of the blood in all cases of diseases of the nervous system. With the improved methods of investigation which we now had, there was absolutely no excuse for any one to overlook this important factor, any more than to neglect to make a urinary examination. A knowledge of the exact state of the blood materially aided the treatment of diseases of the nervous system.

Dr. J. A. Witherspoon, of Nashville, Tenn., believed that a child born with neurotic tendencies should receive especial care at the time of teething and at the period of puberty, when the nervous system was subjected to exceptional strain and irritation. This was especially true of girls, in whom a crisis was often precipitated by an overcrowding of their minds at school, during the development of their nerve force, by the taking away of blood from the genital organs, and by faulty hygienic surroundings. All depressing influences and critical periods had an important bearing in neurotic patients, as they impoverished the blood.

Dr. William Oldright, of Toronto, Can., called attention to the improper hygienic conditions existing in our schools and colleges. Improvement of these conditions would materially lessen the occurrence of blood and nervous diseases.

Dr. Punton, in closing, regretted that every advance in medicine was met by more or less opposition, and he expected his blood theory of nervous diseases to share the same fate, only to be subsequently acknowledged, just as several other of his theories had been in recent years.

**The Association of Hysteria with Organic Diseases of the Nervous System.**—Dr. Philip Zenner, of Cincinnati, read this paper. He said that organic diseases of the nervous system often followed hysteria, but were frequently obscured by the hysterical manifestations. Diagnosis was facilitated by noting the personality of the patient, the relation of symptoms to organic diseases, and the clinical picture presented. Prominent among these were hysterical temperament, stigmata of disease, anæsthesia, paralysis, contractures, and visual changes. In hysteria special attention must be given to globus hystericus and concentric contraction of the visual field. In organic disease, the alteration of the deep reflexes, rigid pupils, and the reaction of degeneration must be noted.

Dr. Albert E. Sterne, of Indianapolis, discouraged the practice of informing patients of their real condition, if at all serious, as it often led to serious results. They should be told only so much as was necessary to gain their intelligent co-operation in the treatment of the disease with which they were afflicted.

**Temperament and Its Influence.**—Dr. Albert E Sterne, of Indianapolis, read this paper, in which he divided temperament into the acid, alkaline, and neutral varieties, each one of which caused diseases peculiar to itself. This study was still in its infancy, but was one of vast importance in its relation to diseases of the nervous system, and was deserving of further investigation.

Dr. William F. Barclay believed that there was more in the theory of temperament than was at present appreciated.

**Bacteriological Diagnosis in all Diseases of the Conjunctiva and Cornea.**—Dr. J. O. Stillson, of Indianapolis, read this paper, in which he set forth the importance of the bacteriological diagnosis in all diseases of the conjunctiva and cornea. Water curettage was advocated in certain ulcers of the cornea. A small stream of either sterilized water or antiseptic solution was thrown against the cornea with sufficient force to dislodge the necrosed epithelium and clean out the ulcer. This method had been found salutary in the hands of the author.

Dr. Dudley S. Reynolds, of Louisville, favored the curette in the treatment of persistent ulcer of the cornea, as this was an infection and required antiseptic treatment. The best antiseptic in his opinion was carbolic acid, applied carefully with the point of a needle so as not to puncture the posterior layer of the cornea.

Dr. Stillson found that the carbolic acid had a tendency to burrow into the layers of the cornea and cause serious separation of these layers, and it was for this reason that he adopted the water curettage.

**Intestinal Auto-Intoxication, Its Prevention and Treatment.**—This was the title of a paper by Dr. W. F. Barclay, of Pittsburg. The author deduced the following conclusions: Daily evacuation of the bowels would prevent decomposition of matter in the intestines, and subsequent auto-intoxication. Rectal injections of water, for the purpose of producing a bowel movement, or for cleansing the bowel, were not approved of, but cathartics were recommended, especially calomel, papoid, salines, saline mineral waters, cold baths, etc. Proper food, at regular intervals, was important.

**Indigestion in Infants and Children.**—Dr. James H. Taylor, of Indianapolis, read this paper. He discussed the causes of indigestion, such as improper food and over-feeding. The treatment consisted in washing out the stomach, ridding the alimentary tract of all irritating matter, and then regulating the diet and time of feeding. He insisted on absolute rest. Medicinal treatment was not so essential. Tincture of nux vomica and arseniate of copper were given.

Dr. Albert D. Sterne attributed the sclerotic change in the blood-vessels of young men to intestinal auto-intoxication. As to the feeding of infants, and even adults, milk, being absorbed and not digested, should always be given alone, and at frequent intervals.

Dr. Henry B. Favill, of Chicago, mentioned the importance of properly using the terms auto-intoxication and auto-infection, as they were not synonymous, and should not be used in that sense. Products of imperfect metabolic activity, such as uric acid, xanthin, etc., he classified under the term of metabolic intoxications.

Dr. J. O. Malsbury, of Peru, Ind., believed that if the system was kept well flooded with water, both inside and out, constipation would rarely result. This was demonstrated in the case of people who were accustomed to drinking large quantities of water, as they were never constipated. If intestinal auto-intoxication existed, the tract should be cleaned out with calomel, and then kept clean by withholding all food. A weak infusion of ordinary tea was to be given, as it was astringent, stimulating, and satisfied the want for food. The best food for infants was cow's milk, well diluted, and mixed with lime-water and a little sugar of milk. Milk should never be boiled, as it destroyed the efficiency of the milk. Plenty of water must be given in the intervals.

Dr. Charles L. Minor, of Asheville, N. C., believed that the use of water by mouth or per rectum should be encouraged in all cases of intestinal fermentation. It stimulated all the emunctories and the liver functions, thus relieving the system of the products of improper metabolism.

Dr. R. E. Haughton, of Richmond, Ind., indorsed the use of water in intestinal intoxication, as it regulated blood pressure, thus preventing decomposition. He took exception to the term metabolic auto-intoxication, as metabolism was a physiological function and not a pathological one.

Dr. Thomas H. Stucky, of Louisville, was a firm believer in colonic lavage, as cathartics would not empty a bowel which had been in a state of rest for some time. He believed in the use of water internally, externally, and eternally, except during meals. Auto-intoxication would never result when food was properly prepared and properly eaten, and the alimentary canal was in a clean condition. The best eliminant was three to four quarts of saline solution, to be repeated as often as necessary.

Dr. James T. Jelks, of Hot Springs, Ark., took exception to Dr. Barclay's reference to the intoxication present in typhoid-fever patients as a result of micro-organisms, for if this was true we would have to resort to the antiseptic treatment in order to destroy these germs. While the germs might start in the intestinal canal, they were rapidly disseminated all through the system, and it was futile to attempt to combat such a fire with a small dose of an antiseptic. Phagocytosis was the real element with which to fight this affection, and it can be done only by the free use of water.

Dr. Barclay said he had learned from experience that the continued use of syringes was detrimental to health.

**Lithiasis.**—This was the title of a paper by Dr. R. Alexander Bate, of Louisville, in which the author, after referring to the etiology and symptomatology, concluded by saying that the only proper treatment of this condition was the free use of salicylates and alkalies.

**Nephrolithiasis.**—Dr. A. H. Cordier, of Kansas City, Mo., read a paper bearing this title, in which he dwelt especially on the clinical diagnosis and treatment of this disease.

**The Therapeutics of Infectious Conjunctivitis.**—Dr. Dudley S. Reynolds, of Louisville, read this paper. He advocated irrigation with saline solution. He condemned caustic applications, believing they were often responsible for many of the disastrous sequelæ and deformities following infectious conjunctivitis.

**Introversion of the Iris.**—Dr. L. W. Bearsdley, of St. Louis, read a paper on this subject.

**The Study of Lung Reflexes.**—The last paper in this section was contributed by Dr. Marian K. Bowles, of Joliet, Ill. She called attention to the fact that examination of the lung should be made more frequently in cases that were clearly not of lung disease, for it often cleared up the diagnosis, as some trifling cause might excite reflex contraction of the fine muscle fibres. This was especially important in life-insurance examinations.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, October 3, 1899.*

Frederick Peterson, M.D., President.

**Cerebellar Tumor.**—Dr. W. B. Noyes presented a boy of five years who had been well up to last June. At that time he had had an obscure illness which had been diagnosed by the attending physician as an auto-intoxication. He had remained unconscious for two days. During July he had been in fair condition. In August it was noticed that he staggered when walking. When sitting down he could move his legs, but there was absolute ataxia. There was a slight spastic condition of the legs which interfered with properly obtaining the knee jerk. Ankle clonus could be occasionally elicited. There were no sensory disturbances of any sort. His mental condition was becoming slowly worse. Examination of the eyes showed papillitis with hemorrhages over the disc. The pupils were dilated and did not respond to light. There had been neither headache nor vomiting. The case was presented as probably one of cerebellar tumor. The speaker said that it was not impossible that the sickness which had occurred last June might have been a meningitis; it was also possible that there was a hydrocephalus.

Dr. George W. Jacoby said that he had been impressed with the general laxness of the body and the bending forward of the thorax. This general loss of muscular tone made him believe the diagnosis of cerebellar tumor to be correct.

Dr. Hughes, of St. Louis, said that while the case suggested cerebellar tumor, it seemed to him not im-

probable that there had been a cerebro-spinal meningitis, and that the present condition was the result of this meningitis.

Dr. Edward D. Fisher inclined to the view that the case was one of cerebellar tumor, although admitting the force of the statement of the last speaker.

Dr. Noyes said that he thought the condition of the eyes alone seemed competent to settle the question of the diagnosis. He had been unable to find the report of a case of hydrocephalus producing optic neuritis, although it might cause optic atrophy when very far advanced. The case was evidently progressing rather rapidly now.

**Brachial-Plexus Pressure Paralysis.**—Dr. William M. Leszynsky presented a young woman having a brachial-plexus paralysis affecting both arms, the result of pressure (see page 583).

Dr. Fisher said that these cases of pressure paralysis were quite commonly observed after operations, as, for example, for appendicitis, but he had never before seen a case in which both sides had been involved. Negligence in attending to the position of the arm during operation was often responsible for such paralysis.

Dr. Fraenkel said that while many cases of post-operative paralysis had been reported, it should be remembered that in some the paralysis had been ascribed to the ether, although in others the influence of pressure had been definitely shown. This made it difficult to hold the surgeon liable in many instances.

Dr. G. W. Jacoby said that the various cases had been recently tabulated, and the conclusion had been reached that all the paralyses could be explained only by pressure. The consensus of opinion at the present time seemed to be that the ether could not give rise to this form of paralysis. Surgical assistants were often very negligent about these matters. For example, he had found an assistant making hypodermic injections of ether and brandy in a case of collapse, directly over the musculo-spiral nerve, and the ensuing paralysis he would have found difficulty in explaining had he not seen these injections being made. Again, he had known it to be positively asserted that there had been no pressure, and yet he had personally seen the etherizer resting his elbows heavily over the patient's clavicles.

Dr. Frederick Peterson said that he had seen even the peroneal nerve affected in this way after ether narcosis. In every case that he had investigated he had found that there had been a possibility of the paralysis having been produced by pressure. The question was of great importance, for he believed it would be perfectly possible for such a paralyzed patient to collect damages from the surgeon on account of such negligence. Nearly all the pressure paralyses occurring at night developed during alcoholic sleep, and he had come to look upon these as occurring in nerves which had been rendered especially vulnerable by ether or alcohol, or, as suggested by Dr. G. W. Jacoby, the inhalation of carbonic oxide in close sleeping-rooms. In cases of musculo-spiral palsy the nerve was generally pressed upon when the patient slept with the arm raised, and the hand under the back of the head.

Dr. Hughes said that the paralyses following the comatose state in epilepsy exhibited local peripheral expressions. Neurologists had been accustomed to consider these as of central origin. His own opinion was that ether was a factor which could not be ignored; that it was a toxic factor, acting on the peripheral cells, thus rendering the nervous system vulnerable, just as did alcohol. He had not yet been convinced that these cases were exclusively peripheral paralyses, and owing to this lack of unanimity among neurologists regarding the causation of these cases their medico-legal aspect assumed grave importance. Many of these paralyses seemed to be recovered from just as in the case of epileptic paralyses, and he was inclined to think that the toxic condition of the brain found associated with etherization was an important etiological factor.

Dr. Leszynsky said that he could not agree with the views of the previous speaker regarding the effect of etherization. When a healthy person was etherized it could hardly be said that the toxic condition could so soon be responsible for the paralysis; it was rather a case of extreme pressure made during unconsciousness. In his own mind there was no question that all of these cases were directly due to pressure made during unconsciousness. Ether, like other stimulants, might give rise to cerebral hemorrhage, or induce hemiplegia of the hysterical type. If these cases were due to a lesion in the anterior horn they would not all result in recovery, as occurred invariably in the class of cases under discussion.

**The Central Nervous System in Acute Malarial Infection.**—Dr. James Ewing read this paper. He introduced the subject by reporting the three following cases:

Case I.—Æstivo-autumnal malaria, with marked cerebral symptoms and infection, with a single, well-defined group of parasites. The patient was a soldier who had just returned from Cuba. The stupor lasted thirty-six hours prior to death. Two days before death there had been many ring-shaped organisms in the blood. The stupor began twelve hours after sporulation occurred. At the autopsy the viscera showed the lesions of severe malarial infection. The capillaries of the cerebrum, cerebellum, medulla, and cervical cord contained a large number of cells harboring parasites. Many capillaries were occluded by thrombi. The ganglion cells showed everywhere a reduction in size, irregularity and splitting or loss of the chromatic bodies. Death was due to the massing of the parasites in the capillaries. The case was a good example of comatose malaria of the cerebral type.

Case II.—This patient had chills on alternate days for several days, and on admission had a pulse of 110, and was much prostrated. There were marked insomnia and mild delirium for a while; then the delirium became more marked, and finally there was coma, lasting for some time before death. There was no evidence that the coma was uræmic. The temperature reached 108° F. shortly before death. On October 12th the blood contained an enormous number of ovoidal, spherical, and crescentic bodies. On October 25th, or eight hours before death, very few crescents could be seen. None of the younger forms was found. The antopsy showed moderate œdema of the brain, the basal vessels normal, and very few parasites present. The deposit of pigment in the brain was slight. Throughout the cortex the cells showed no marked change further than a uniform diminution in the chromatic substance. In many of the pericellular lymphocytes were peculiar structures—elongated fibres or rods with tapering ends—of undetermined nature. Similar deposits were found in other cases of malaria, and in one case of tuberculous meningitis. The chief feature of this case was the prolonged delirium and coma, yet the post-mortem examination showed far less change in the kidney than was usually seen in profound malarial infection.

Case III.—This was a case of fatal malaria associated with hæmoglobinuria. This man had contracted malaria in Santiago in July, 1898. He was comatose, extremely emaciated, excessively anæmic, and moderately jaundiced. He was at Camp Wykoff for three days prior to death. The dura and pia were distinctly jaundiced. The cerebrum, cerebellum, and

medulla showed the usual injection of vessels with blood, but the vast majority of the vessels were free from the parasites. An abundant deposit of hæmatoidin in the kidneys was interesting.

Commenting upon the foregoing cases, the speaker said that when the brain cortex was markedly brownish it indicated usually the presence of a large number of parasites, but this was not an invariable rule. The majority of cases of comatose malaria did not exhibit the massing of the parasites in the brain. Of eight cases in which he had examined the brain after death, in none was there a distinct brownish discoloration of the brain. Hemorrhages had been found in some cases, as had also a moderate degree of œdema. Usually the parasites were uniformly distributed in the brain and cord, but a case had been reported in which they had been localized in the medulla. The number of these parasites was often enormous, and complete occlusion of the vessels was not at all uncommon. While most of the fixed pigment was found in the endothelium, the parasites were rarely seen in the endothelial cells. To the general condition of the obstructed circulation it was probably safe to refer the cerebral symptoms observed in these severe cases of malarial infection. The ganglion cells, in cases of comatose malaria, had been studied, and the changes found to consist chiefly in the various degrees of chromatolysis. The dendrites were usually involved before the cell body. The ganglion cells appeared to suffer less than in the average case of typhoid fever. The mere presence of the parasites in the tissues seemed to exert no bad influence except in a mechanical way. In one of the cases reported in the paper the deepening of the coma could be apparently connected with the progressive filling of the capillaries with the parasites and the formation of thrombi. In the other two cases the parasites were few and the pigment was scanty. In both of these cases the malarial infection was exceedingly severe. These cases showed that the coma of malaria was not always referable to the presence of the cerebral parasites. Of the writer's sixty-four cases reported of malarial coma, there were five simple tertian infections. In the æstivo-autumnal cases, with crescents only in the blood, there were thirty-four instances from the Montauk camp. Coma appeared to be rather frequent in cases showing only crescents in the blood. Crescents did not exhibit such a tendency to unequal distribution as did the fertile forms. From the condition of the viscera found in the second and third cases reported—and this variety occurred especially in cachectic individuals in whom the disease had existed for some weeks—it seemed probable that the coma was the result of the general and profound malarial infection. The writer did not believe that much importance should be attached at the present time to the condition of the ganglion cells in malaria. When the coma resulted from the massing of the young parasites in the brain, it was generally gradual in onset, and the prognosis was very unfavorable. In some cases the coma developed suddenly, and was more amenable to appropriate treatment. The general clinical character of these cases indicated that an embolic process was concerned in their causation. Of eleven cases of the first class, reported by the writer, ten proved fatal. To summarize: The three anatomical conditions were: (1) The mechanical obstruction of the cerebral capillaries by large numbers of young parasites; (2) an embolic process causing an occlusion of some vessels (usually temporary) by parasites or pigmented leucocytes; and (3) a general toxæmia, such as might occur in other infectious diseases, the blood showing few, if any, autumnal rings.

Dr. W. B. Noyes said that two years ago he had seen at the Columbus Hospital, in the service of Dr. C. H. Lewis, a case showing coma, stertorous respiration, partial paralysis, and irresponsive pupils. The blood taken from the spleen at autopsy showed the presence of pigmented leucocytes and parasites of the æstivo-autumnal variety. Sections from every part of the brain, without staining, showed that the walls of the capillaries were infiltrated with pigment. The absence of the parasites and the enormous amount of pigment were especially noteworthy. In the other organs of the body the usual lesions of pernicious malarial fever were found. In this case the diagnosis during life had been cerebral hemorrhage by almost every physician who had seen the case—certainly the clinical appearances were the usual ones found in cerebral hemorrhage.

Dr. Lewis A. Conner thought the jaundice might explain some of the comas that were otherwise inexplicable. It was surprising sometimes how an apparently moderate degree of jaundice might be associated with very marked cerebral symptoms.

Dr. Fraenkel said that he looked upon most of the nervous consequences of malaria as due to toxæmia. He was reminded of a case that had presented a well-defined picture of aneurism at the base of the brain. The patient had been under observation for a considerable time without noteworthy symptoms until suddenly he had chills and fever. At that time he was in a room in the hospital in which there had been malarial fever. The chills and fever recurred regularly for two or three days, and then he was removed to another room. He then had an acute maniacal seizure, and after half an hour talked in a typical paranoiac fashion. He next became rational, but developed the same train of symptoms the next day at the same time. The blood showed the æstivo-autumnal parasites. The man finally recovered, and was well at the present time. Another case was cited bearing upon the view that a malarial toxæmia was responsible for most of the nervous symptoms. When first seen this person had been sick only two hours. He stated that he had suddenly become unconscious, and that this had been immediately followed by an urticarial eruption. He had a very slow pulse and some fever. On the third day there was a severe chill, some jaundice, and a temperature of 104° F. The blood showed the presence of the parasites of æstivo-autumnal malaria. The patient recovered in due time, only to have a similar attack about the same time the following year. Such a case, the speaker thought, could hardly be explained by mechanical obstruction; it was rather an example of the effect of a general toxæmia.

Dr. Hughes said that the paper was very satisfactory in that it explained certain old and well-known clinical facts. Williamson, of England, had been one of the first authors to refer to the effect of malaria on the nervous system. A case of infantile paraplegia was recalled which he had seen many years ago. When first seen the child had been unable to sit or stand. The speaker had at once suspected malaria, and a vigorous course of quinine had resulted in a rapid and seemingly miraculous cure. He was inclined to believe that the effect of malarial infection was principally spent upon the vasomotor system.

Dr. William Hirsch reported a case of a gentleman sent to him from the South about one year ago, with a diagnosis of spinal tumor. The symptoms had been atrophy of the muscles of the left shoulder girdle, and associated with intense pain. The patellar reflexes were exaggerated. After having had the case under observation for some time, and studying the previous history very carefully, he had become convinced that this was not the correct diagnosis. The patient gave a history of having had a somewhat similar attack some time before, which had been recovered from. While under observation the man had devel-

oped a typically malarial temperature, and this had been associated with splenic enlargement. Examination of the blood at that time had been negative. After about six weeks of anti-malarial treatment recovery had been complete. A very peculiar symptom in this case was a decidedly tender swelling over the sternum. This had disappeared as the patient had improved. The man, against advice, had returned to his home in the South, and when seen again, a few weeks ago, had been in a worse condition than the year previous. The left clavicle then exhibited a tender swelling, like that observed previously over the sternum. There were similar swellings over one ulna and on one portion of the skull. He was now improving rapidly under anti-malarial treatment. The case was reported because of this peculiar affection of the bones.

Dr. Teller, of Memphis, said that he practised in a district in which malaria was exceedingly common and very malignant. In his neighborhood these peculiar neurotic manifestations of malaria were so common as to make the physicians be constantly on the lookout for them. The cases of cerebral congestion were all too common, and very frequently proved fatal. The physicians of his locality looked upon the disease as a profound toxæmia.

Dr. Ewing said that he had been especially interested in the remarks of one of the speakers concerning cases exhibiting jaundice. These cases commonly showed at autopsy profound and peculiar changes in the liver. In the case reported by Dr. Hirsch there were certain features that seemed to him to point to syphilitic infection. In conclusion, the speaker said that the medical profession was too prone to jump to the conclusion that a disease was malarial because it seemed to respond to the administration of quinine. A very large number of nervous conditions reported that had been referred to malaria by the older writers should be excluded at the present time, because they had not been properly authenticated according to modern notions.

## Reviews and Notices.

Kirkes' Handbook of Physiology. Fifteenth American Edition. Revised by Warren Coleman, M.D., Professor of Physiology in the Woman's Medical College, New York, etc., and Charles L. Dana, A.M., M.D., Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School, etc. New York: William Wood and Company. 1899.

The latest revision of this well-known and authoritative text-book on physiology calls for no extended review. When one edition follows another so rapidly there is, naturally, not much in the way of revision. Yet so steady is the advance in all branches of medical science, that even here it has been necessary to make some additions in order to bring the work thoroughly up to date. These changes are in the main slight, yet they are quite numerous and all are of sufficient importance to justify the revision. The most important of these changes are in the description of the cell, of the ductless glands, and of the coagulation of the blood. The book is illustrated with many black and colored woodcuts, and one chromolithographic plate of blood spectra.

A Strange Discovery. By Charles Romyn Dake. New York: H. Ingalls Kimball. 1899.

This tale, the author of which is a physician, is intended as a sequel to Poe's uncompleted "Narrative of A. Gordon Pym." It describes how the author and two friends found Dirk Peters, the companion of Pym in his wanderings, in a town in southern Illinois, and learned from him what happened after they had passed through the veil and past the gigantic female form that seemed to block their way. It is probable that Poe, had he finished the tale, would have taken his readers into Symmes' Hole; but the island on which Dr. Dake lands us is just as interesting—and just as likely to exist. The author has much to say also of the two companions who shared in the "strange discovery" of Dirk Peters, and it is possible that this sketch is from life. The town in which the scene is laid is the same, with slightly altered name, as the one in which the author actually lives, and the two companions are physicians—one a regular, the other a homœopath. They have many discussions, in which (the author is himself a homœopathic physician) the homœopath usually comes out ahead.

The Mineral Waters of the United States and their Therapeutic Uses, with an Account of the Various Mineral Spring Localities, their Advantages as Health Resorts, Means of Access, etc.; to which is added an Appendix on Potable Waters. By James K. Crook, A.M., M.D., Adjunct Professor of Clinical Medicine and Physical Diagnosis at the New York Post-Graduate Medical School; Attending Physician to the Post-Graduate Hospital; Member of the Medical Societies of the County and of the State of New York, Fellow of the New York Academy of Medicine, etc. New York and Philadelphia: Lea Brothers & Co. 1899.

It is many years since a work on the mineral springs of this country has been published, the latest prior to the appearance of Dr. Crook's work having been, we believe, Bell's "Climatology and Mineral Waters of the United States," published about fifteen years ago. The present book will, therefore, be welcomed by all who are in need of trustworthy information on this subject either for themselves or for their patients. The work is divided into two parts; the first treating in general of mineral waters and their uses, the second containing a description, in most cases with analysis, of the waters of all the important and many unimportant mineral springs in this country. The latter are arranged alphabetically by States, so that they can be readily turned to, and if the State is not known an index serves to direct the reader to the description he seeks. This book is a valuable addition to the literature of balneology.

Die Leitungsbahnen im Gehirn und Rückenmark. Ein Handbuch für das Studium des Aufbaues und der inneren Verbindungen des Nervensystemes. Von W. v. Bechterew, o.ö. Professor der Kaiserl. medizinischen Akademie, Direktor der Psychiatrischen und Nervenklinik zu St. Petersburg. Deutsch von Richard Weinberg, Assistent des Jiorgeff-Dorpater Anatomischen Institutes. Zweite, vollig umgearbeitete und stark erweiterte Auflage. Mit 589 Textabbildungen und 1 farbigen Tafel. Leipzig: Arthur Georgi. 1899.

The last decade has been a period of remarkable activity and of material advance in the domain of neurology. In the process of differentiation and in the demand for special knowledge, this department of medicine has become increasingly a more and more exclusive field of operation. Notwithstanding the complexity and the intricacy of the nervous system, the study of its diseases has been conducted upon a scientific basis, and in the hands of competent observers the diagnosis is usually a matter of great precision, being almost a direct deduction from a knowledge of the anatomy and physiology. Recent investigations by modern methods have added much to this knowledge, gross and minute, the greatest impetus being given the movement by the refinements in staining and differentiating procedures that have been effected. Among the modes of inquiry that have been pursued in bringing neurological science to its present advanced position may be mentioned the comparative study of serial sections, the treatment of tissues with stains and other chemical reagents, observations in comparative anatomy, a study of the development of the nervous system in the embryo, of the results of developmental defects or of atrophy, of secondary degenerations, physiological or vivisection methods, pathological methods, embryologico-pathological methods, and pathologico-physiological methods. In this field of activity Bechterew and his pupils have played a conspicuous part, and a not inconsiderable portion of the present work represents the results of their labors. At the same time the contributions of other investigators have been given due consideration, so that we have here an authoritative and comprehensive description of the conduction paths of the

brain and spinal cord. The work is divided into six sections, the first of which deals with the methods for studying the course of fibres in the central nervous system. The second, third, fourth, and fifth sections take up successively the conduction paths of the spinal cord, the medulla oblongata and the basal ganglia, the cerebellum and the cortex, and the subcortical structures. In the sixth section the conduction mechanism is discussed, and in the final section a general survey is made of the entire system of conduction-paths in the central nervous system. At the end of each section is appended the bibliography relating to the subjects discussed in that section. The illustrations are numerous and excellent, and for the most part original. The book is altogether an admirable exposition of the important subject with which it deals, and it must be conceded to be a valuable contribution to the histological anatomy of the nervous system.

## Therapeutic Hints.

**Rigid Perineum.—**

℞ Chloroformi ..... ℥ ij.
Etheris ..... ℥ i.
Spirit Colognien ..... ℥ i.
M. S. Apply.

—Southworth.

**Rheumatism, External Application for.—**

℞ Acid. salicyl. pulv ..... ℥ i.
Ol. terebinth ..... ℥ i.
Lanolini ..... ℥ viij.

The skin is first to be cleansed with soap and water. Friction should last for five minutes. Wrap the limb in cotton to preserve an even temperature. Repeat the treatment daily.—Husson.

**To Quiet Patients After Operations.—**

℞ Liquor potassii citratis ..... ʒ ss.
Spir. ætheris nitrosi ..... ℥ i.
Tinct. aconiti ..... gtt. i.
Morphinæ sulphatis ..... gr. ⅛
S. In water every third or fourth hour.

—Brinton.

**Anæmic Strumous Children.—**

℞ Acidi arsenosi ..... gr. ⅛
Ferri sulphat. exsiccat.,
Potassii carbonat ..... āā gr. viij.
M. fiant pil. xii. S. One pill thrice daily after meals

—Graham.

**Enlarged Lymph Nodes.**—When surgical intervention is inadvisable:

℞ Ichthyol ..... ℥ i.
Ung. hydrargyri
Ung. belladonnæ ..... āā ℥ i.
Ung petrolei ..... ℥ iv.
M. S Externally.

—Keen.

**When the Taste and Smell of Chloroform are repugnant the following mixture is recommended:**

℞ Aq. chloroformi ..... ʒ vi.
Spir. menth. pip.,
Spir anisi ..... āā ♏ iv.
Filter after twelve hours.

—Weber

**Acute Dysentery.**—Sulphate of soda (or magnesia) is given on the first day of the disease, and on the second, third, and fourth days, every three hours, a capsule containing

℞ Magnesia ..... gr. iv.
Bismuth subnitrate ..... gr. vi.
Powdered ipecac ..... gr. i.
Powdered opium ..... gr. ⅛

—Sodré.

**La Grippe.**—In nine cases out of ten all that has been necessary was to soak the feet, tell the patient to take a teaspoonful of the following prescription, and then insist upon his staying in bed for forty-eight hours:

℞ Pilocarpin. hydrochlor ..... gr. ss.
Morphinæ sulph ..... gr. i.-iij.
Aquæ ..... ℥ iij.
M. S. Teaspoonful every quarter of an hour as directed.

Especially during this epidemic have I become convinced that apomorphine is a valuable expectorant:

℞ Ammonii chloridi ..... ℥ ij.
Apomorphinæ hydrochlor ..... gr. i.
Mist glycyrrhizæ comp.,
Syrupi ..... āā ʒ iss.
M. S. Dessertspoonful every two or three hours.

—J. Howe Adams, *Medical Times*, September.

**Tonic in Incipient Phthisis.—**

℞ Acid. arsenosi ..... gr. ss.
Ext. nuc. vom ..... gr. iv.
Ferri reducti ..... gr. ij.
Quinin. hydrochlor ..... gr. xx.
Ft. pil. No. xx.

**Diarrhœa of Typhoid Fever.—**

℞ Acid. sulph. aromat ..... ℥ ij.
Fl. ext. hæmatoxyli ..... ʒ ss.
Spir. camphoræ ..... ʒ ss.
Syr. zingiberis ..... ℥ iij.
M. S. Two teaspoonfuls when the stools exceed four in a day.

—*Medical Times*, September.

**Feeble Digestion.—**

℞ Tinct. ipecac.,
Tinct. calumbæ,
Tinct. gentianæ ..... āā ℥ iij.
M. S. Take five to ten drops in a little water after eating, and repeat the dose in a half-hour, and again in an hour.

—Mathieu.

**To Relieve the Pain in Cystitis.—**

℞ Ext. hyoscyami ..... gr. ss.
Camphoræ monobrom ..... gr. ij.
Morphinæ sulphat ..... gr. ss.
Ol. theobrom ..... q.s.
M. et ft suppos No. i.

**For Irrigation of the Bladder.—**

℞ Acidi borici ..... ℥ i.
Sod. borat ..... gr. xxx.
Sodii chloridi ..... gr. xv.
Aquæ ..... O ij.
M. S. Warm to 100° or 105° F. The irrigation can be performed through a double-current catheter or a meatus nozzle, after the method suggested by Janet of Paris.

—George T. Howland.

**When Uræmia Threatens.**—Use the hot pack over the kidneys and:

℞ Pilocarpin ..... gr. ss.-i.
Hydrochloric acid (dilute) ..... ℥ ij.
Distilled water ..... up to ʒ ij.
M. S. Teaspoonful every three hours.

—N. A. Kremer, *The Medical and Surgical Monitor*, vol. ii., No. 6.

**Pertussis.—**

℞ Sodii benzoat ..... gr. lxxij.
Sodii bicarb ..... gr xlviij.
Ammonii chloridi ..... gr. xxiv.
Aq. chloroformi ..... ʒ i
Aq. anisi ..... ℥ iij.
M. S. ℥ i.-ʒ ss. in a little milk, every four hours.

—Burney Yeo.

**Laxative.—**

℞ Rhei pulv ..... 20
Sodii bisulph ..... 15
Sodii bicarb ..... 5
M. ft. pulv. S. One dessertspoonful in a wafer at bedtime

Or:

℞ Rhei pulv ..... 10
Tartar depur ..... 20
M. ft. pulv. S. As above.

—Leube.

**Dropsy.—**

℞ Uropherin salicyl..... 5.0
Aq. destill..... 120.0
Vanillini..... 0.001
Muc. acaciæ,
Syr. simplicis.....āā 15.0
M. S. 3i. t.i.d.

—Schmidt.

**In Nephritis.—**

℞ Tinct. grindeliæ rob..... 30
Tinct. convallariæ..... 10
Tinct. scillæ..... 5
M. S. Fifteen drops three or four times daily.

—Huchard.

℞ Potassii bitartratis..... 30.0
Potassii sulphatis..... 15.0
Pulveris scillæ..... 8.0
Antimonii et potass. tartratis..... 0.06
M. S. One teaspoonful in a tumblerful of water every four hours until active purgation and free diuresis occur.

—Eberle.

**Tetany.**—Up to the present time no constant anatomical lesions have been demonstrated in tetany. Its symptoms and course all indicate that it is a neurosis probably depending upon disturbances of nutrition in the nerve cells of the spinal cord and medulla.—Holt.

The nature of the disease is unknown, but it probably depends upon the action of some toxic agent in the motor-nerve cell.—Osler.

---

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

COMING SESSION—CONGRESS OF INSTITUTE OF PUBLIC HEALTH—MARQUIS OF LORNE'S SPEECH—VACCINATION RETURNS—LEICESTER RECALCITRANT—ANALYSTS' DEPUTIES—A NONAGENARIAN DOCTOR—INQUEST ON A DOCTOR—DEATHS OF MESSRS. VOSE SOLOMON, FOGO, AND JOSEPH WHITE.

London, September 29, 1899.

There are plenty of doctors now in town. Nearly all have returned after their autumn holidays, and the teachers are ready to take up their work at the opening of the winter session on Monday. The societies will follow one by one, medical work will shortly be in full swing, and the long vacation of 1899 a memory.

The congress season is also over. The Institute of Public Health, which met on the 21st, closed yesterday. Its proceedings were very various, the subjects ranging from engineering to tuberculosis, from domestic hygiene to cremation. Dr. R. McNeill would have domestic science taught as a mode of improving public health, and he included in his purview the theory and practice of cooking, laundry work, and dressmaking. This will show you the wide range of subjects admitted for discussion at this congress. Tuberculosis was introduced by Dr. Ransome, who urged on local sanitary authorities their duty in regard to this disease. Mr. Whittaker had a paper on the treatment of sewage by microbes, in which he vigorously criticised the local government board's attitude, eliciting cheers from the audience, which showed they held decided views on this matter. Dr. Graham handled smoke abatement, and urged that the community should exert its influence to bring about better administration of the public health acts and improvement of the law. He hoped to see better protection from this evil before the close of the century.

The president, the Marquis of Lorne, in his opening address alluded to vaccination and the controversy that has raged about it, as follows: "When we reach the end of another century and many other diseases besides smallpox are capable of being prevented in like manner, shall we see, as now, the very immunity and safety conferred by science produce a disbelief in the presence of danger, and the chief bulwark against the microbes of disease thrown down so as to give a fresh lesson to the short memory of the people?" This sensible and moderate remark reminds one that a parliamentary return issued on Tuesday from the local government board shows that the mass of the public still believes in vaccination; for notwithstanding the large number in certain localities who took advantage of the conscience clause in the last act, there was an actual increase of successful primary vaccinations during the first six months of this over the corresponding period of last year. The numbers are, for 1898, 278,588; for 1899, 355,987. Thus there was an increase of 77,399. The figures cover 646 unions, of which 479 show increases, but 165 show decreases. In some of the localities in which neglect or opposition had been most rife, there is an increase; for example, Ashby-de-la-Zouche has risen from 20 to 435, and Melton-Mowbray from 32 to 503. Even Leicester with all its obstinate anti-vacs returns 88 as against 32.

With regard to this town another stage has been reached in its contest with the superior authorities. On Tuesday night a solicitor's clerk attended the meeting of the guardians and served each of the recalcitrant members with a copy of the writ of mandamus on behalf of the local government board. One of the members said many proceedings had yet to be taken before they entered the prison doors. The vice-chairman declared the guardians would not withdraw from their position, and the board then adjourned.

Some medical officers of health are solemnly warning parents of the risks children incur by partaking of ice cream. One declared that recent samples showed half a million microbes in the thousandth part of a pint. This is a comparatively pure sample against one in which Dr. Stevenson's bacteriological assistant calculated there were more than twenty millions. In this case there was a prosecution, and Dr. Stevenson attended as a witness, but as he had to admit that he had not made the analysis himself the magistrate dismissed the summons. Naturally enough, the question is thereby raised as to the practice of entrusting such work to assistants engaged by public analysts. I believe the system is common enough, and that the assistants are men well qualified for the work. But there is no guarantee for their qualifications, and the authorities who appoint the analysts may well object to the system, while in cases brought into court this prosecution shows what is likely to occur. The fact is, that many of our analysts hold several appointments under the acts, and could not possibly perform all the analyses personally. I have for many year known this and seen how the work was done. As a rule there is sufficient superintendence in the laboratories, and the assistants are quite competent for their work. Nevertheless the public will not be satisfied with a system thus liable to break down, and without a voice in the selection of assistants. I should add, however, that the court decided in 1894 that it is not necessary for the analyst to carry out all the processes himself if they are done under his supervision.

Dr. W. W. Morgan, of Newport, Mon., celebrated his 90th birthday on the 24th, and received special congratulations from his brother Freemasons and other friends. He told the story of his examination in 1835, which is very amusing: "I was the young man from the country, and found the examiners sitting together horse-shoe shape, while I had to face them. One of them said, 'Mr. Morgan, are you a native of

Wales? I am, sir,' I replied; 'I suppose you took me for a foreigner.' My hair was long, curly, and black as a raven. 'I certainly did,' he returned. 'Well, sir,' I said, 'I assure you I can boast of not having a drop of English blood in my veins, much less a more foreign one.' 'Well done, Welshy,' cried my questioner—it was Sir Astley Cooper, who had married a Welsh lady, and the other examiners roared with laughter, during which I was led by an attendant to 'Paradise'—the room where successful candidates were taken—and I knew I had passed; but fancy my temerity in saying that to a full board of examiners."

An inquest on the body of Dr. Dick, of Eastbourne, shows that he met with his death through a mistake of his own. Having supplied medicine to one of his patients, he was sent for next day and told that the first dose had made her very ill. He told her this could not be, and to reassure her poured out a dose and swallowed it in her presence. He admitted it was nasty, but declared it was innocuous and that he would take another dose on leaving. He did so, and rode home on his bicycle, but on arrival symptoms of poisoning had appeared, and he was only able to suggest the stomach pump. Medical neighbors were promptly in attendance, but he sank rapidly, in spite of all treatment. Analysis showed that the medicine contained strychnine. The patient, who took only one dose, recovered. Two bottles were found in the deceased's surgery, near to each other, neither labelled (!), one containing chloroform water, the other solution of strychnine.

Mr. James Vose Solomon, F.R.C.S., consulting surgeon to the Birmingham Eye Hospital, died on the 20th, aged eighty-two years. In the course of his long and honorable career he had served in various offices, but those to which he was most devoted were connected with ophthalmology. Thus he was for a considerable time professor of this subject at the Queen's College and surgeon to the eye hospital. He was a member of our ophthalmological society as well as of the International Congress. He contributed numerous papers on his specialty to the ophthalmic and other journals.

The deaths are also announced of: Surgeon-General J. M. S. Fogo, late of the Ordnance Medical Department, aged seventy-seven years. Joseph White, F.R.C.S. Ed., consulting surgeon to the Nottingham Hospital. He was president of the British Medical Association in 1892, the year it met at Nottingham, and those who attended that meeting will remember his kindly courtesy. He died on the 24th, at Eastbourne, aged seventy-seven years.

## JOTTINGS ON A JOURNEY.

To the Editor of the Medical Record.

Sir: A tour which combined the quest for professional knowledge with recreation may furnish matter to interest some readers. The ophthalmological congress at Utrecht and the otological congress at London were the principal aims. But various opportunities arose outside of these great events which impressed the writer, and he simply proposes to set forth some notable things which seem to him worthy of mention. A visit was made to Pompeii, another to Vienna. Every one knows about the wonderful reproductions in the museum at Pompeii of the bodies found embedded in the ashes, one a corpse, one a woman during the last months of gestation—but the guide did not discern the beautiful specimen of a fractured femur properly mounted, which showed perfect bony union, but with a deformity amounting to a complete right angle and which must have crippled the patient and entailed a shortening of not less than six inches. This was a specimen of surgery nearly two thousand years ago.

Six weeks later I was inspecting the working of the sideroscope as it is used by Professor Fuchs, in Vienna. It is a magnetic needle furnished with a mirror, contained in a room from which all iron is excluded, and its deflections, imaged by electric light upon a scale, are viewed by a small telescope; and although the unavoidable vibrations of the building give rise to some errors, so delicate is the needle that it will respond to the presence in the eyeball of a particle of iron less in bulk than the head of an ordinary pin. Some experimental trials, not upon patients, convinced me that the claims made for the apparatus were not exaggerated. Such is a sample of the splendid achievements of scientific surgery of the present day, in a single department.

I want to call especial attention to what has been wrought in diagnosticating the presence of foreign bodies in the eye. The sideroscope can tell us with amazing clearness when a bit of iron has penetrated the eye. But it says nothing regarding substances which are non-magnetic, brass, lead, stone, etc. Neither can it determine the exact position of a bit of iron within the globe, nor even whether it may not have passed beyond into the orbit or elsewhere. By means of the Roentgen rays (*x*-rays), some precision has been attained in localization. This has been done in Boston, in New York, in Philadelphia, and elsewhere in our own country, and I saw a fair skiagraph in Professor Fuchs' cabinet. But it has been reserved for a London surgeon, Dr. Mackenzie Davidson, formerly of Aberdeen, to bring the use of *x*-rays to a degree of exactness and to avail himself of stereoscopic methods by which, under an exposure of eight seconds, the size and locality of a foreign body can be designated in the eye with absolute certainty; and by longer exposures and with some modifications of method, the same can be done with equal certainty in other parts of the body. Mr. Davidson exhibited his apparatus at the Utrecht congress; he showed numerous skiagraphs, and he explained his method, according to which, by mechanico-geometrical or trigonometrical methods, the depth and position of a foreign body can be recognized in three minutes after the needful pair of skiagraphs have been secured. He has spent two years in bringing his method to its present status, and he now is sought for in London on all serious occasions to make the localizing diagnosis of foreign bodies. I had the privilege of two hours' interview with him at his rooms, and he went through all the details of detecting a foreign body placed on the lower lid. The chief and fundamental improvement with him is in the Crookes tubes. He places a small flat disc at the focus of the concave reflector (the anode), and is most careful to find its focal point, and there he puts his plane aluminum reflector, which has at its centre a bead of osmium, a metal extremely dense, heavy, scarce, and expensive. Unlike all other metals it does not fuse under the concentrated *x*-rays, and from it they emanate in straight lines. It is well known that they cannot be refracted or reflected. But from the osmium bead, which is never bigger than a split dried pea, and which may be either rough or smooth, these subtle rays proceed in such pencils that an interfering object is made to cast a small and wonderfully sharp shadow on the photographic film. Mr. Davidson's method is set forth in the *British Medical Journal*, December 3, 1898, and January 1, 1899.

Another notable achievement in ophthalmology was presented by Professor Dimmick, of Innsbruck, who showed good photographs of the living human fundus oculi!—not only of the nerve, but also of the macular region. He has succeeded in obviating the damaging influence of the corneal reflex which has been the

stumbling-block to all experimenters for thirty years, and of which the writer knows much by personal experience. In the same connection, because analogous, may be mentioned a new demonstrating ophthalmoscope devised by Dr. Walther in Professor Snellen's clinic at Utrecht. It is marvellously clear and free from reflex: one-half of the pupil is used for illumination and the other half for the emergent rays to make the image, which is projected upon a table. Of course this device is not new (the writer employed it thirty years ago), but various details are introduced which remove the disturbing elements hitherto encountered and give a clean, bright picture of about the size seen with the upright image. By this apparatus we shall be enabled to make pictorial records of ophthalmoscopic cases which in the next ten years will greatly enrich our literature.

Other things which greatly impressed me related to methods of projecting upon a screen the microscopic sections of tissues, exactly as they come from the stage of the microscope. The finest apparatus was in the clinic of Professor Fuchs, and at Utrecht similar demonstrations were exhibited by Dr. Dor. At Vienna I was delighted with the beauty and perfection of the pictures thrown on the screen by an apparatus made by Zeiss, with electric light and appliances for annulling the destructive effect of heat upon the slide. The picture was bright, sharp, full of detail, and about thirty inches in diameter. Why may not we in America use arrangements equally perfect? We do this work, and I am not one to decry what we do; but the only aim in science is the very best. The Zeiss apparatus costs 1,000 gulden, rather less than $500. What is that among us, and why should not our methods of teaching at least equal those of our European confrères? Here I beg to express the decided opinion that no charitable institution or hospital will ever attain its highest efficiency or truly fulfil the purposes of its founders and supporters, unless medical and scientific investigation and instruction go hand-in-hand with the treatment of the sick and disabled. We are learning this lesson in our country, but it has not yet been apprehended as it should be. There can be no high and real charity which does not rest on knowledge; and this must not be a stationary, or historic, or even purely clinical knowledge. It must deal with the present and reach forth into the unknown. It requires laboratories, complicated and apparently unnecessary apparatus. It must deal with questions of theory and follow nature into her inner labyrinths where dwell the mysteries of life. Only by assuming this attitude can charitable institutions hold their right to care for the sick and helpless. Besides investigation instruction must not be neglected; one is brother to the other; one helps and promotes the other. The man who teaches may not always be a good investigator; he may not have the time or the gift for patient study, but he must be in the closest touch with his brother of the test tube and microscope and bacteriological research.

At the Utrecht congress, Professor Leber delivered a most instructive discourse on his favorite theme of the secretion and excretion of fluids within the globe. His remarkable modesty was sorely tried by the applause which greeted him. Another splendid effort was a résumé by Mr. Priestley Smith of his experiences in cases of strabismus convergens during the past three years. His clear, precise, and classic English would have been a charm to a mere rhetorician, but his conclusions, carefully guarded and logically wrought out, will stand almost on a plane with his imperishable work upon glaucoma. A point which he conspicuously brought out was the urgency of dealing with strabismus at a very early age, that the cerebral function of binocular vision may be duly educated. It is this which forms the barrier to success by usual modes of treatment when the squinting subjects have reached the ages of seven or more years. Mr. Smith would employ glasses as early as they can be carried on the face, and would operate under two years of age. The writer has operated at the age of one year.

A matter not so important perhaps is an improvement in artificial eyes devised by Professor Snellen, and of which samples were exhibited. They are made by Muller, of Wiesbaden, Germany. The modification consists in laying a cover upon the back of the shell, which may be flat or concave, and in some instance it is modelled after a plaster cast of the orbital cavity. Weight is not noticeably increased, and the advantage gained is the great improvement in appearance (cosmetic effect), and the diminished tendency to unpleasant catarrhal secretion, and probably it will be found after sufficient trial that there will be much less tendency to the formation of bridles and symblepharon. This may do away with the practice of Mules' operation, toward which many oculists have a feeling of uncertainty. The writer found some who approved it and others who rejected it. If a good artificial eye can be worn so as really to resemble its fellow, we gain in therapeutics and we also gain in pathology, because we shall be less indisposed to enucleation.

The otological congress at London brought together a large number of well-known aurists of Germany and France and the continent, as well as from Great Britain, and a few from the United States. A great feature of the assembly was the wonderful museum of pathological specimens, gathered with great trouble, mostly from British cabinets, some from other places. The display of instruments was very large. Mr. Urban Pritchard (who was wisely and wittily called the urbane Pritchard) kept a steady yet firm and gentle hand on all the proceedings both scientific and social. English hospitality, proverbially profuse, surpassed its own record. Among notable men present were Professors Politzer and Lucae, both of whom gave no sign that the ashes of age had yet dimmed their intellectual fires. The topics of discussion ran greatly to mastoid lesions; troubles of the middle ear proper, especially operative proceedings on the ossicula, did not receive much attention. A most interesting paper with lantern pictures was read by Dr. Alden Turner, of London, on the cerebral origin and relations of the acoustic nerve; other highly interesting lantern demonstrations were made by Dr. Birmingham, of Dublin, on the topography of the facial nerve in its relation to mastoid operations; also by Mr. A. H. Cheatle, of London, on the petro-squamosal sinus. Mention of this brings to mind a most valuable and practical paper or address by Professor Panas, in Utrecht, on paralysis (possibly double), of the sixth nerves from injuries to the skull, whereby a fragment of the pars petrosa penetrates the above sinus where the sixth nerve crosses to the cavernous sinus. This was illustrated by some skulls in which the splinter of bone was seen entering the injected sinus, and causing the mischief mentioned: the subjects were young persons. There was a great wealth of otological papers, but the feeling remained on the writer's mind that otology as practised in the United States can hold its own with European competitors.

Such are some of the suggestions gathered from a flying trip, but no record can give account of the innumerable and precious opportunities of chatting with able men on obscure points and vexed questions, and new suggestions which are not found in papers and never get into text-books. Most truly is it true of medical congresses that the proper study of mankind is man.

Henry D. Noyes, M.D.

New York, September 23, 1899.

## FAITH CURE AND THE LAW.

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record for October 7th, just received, I have read Dr. Steele's article under the above heading. He closes by saying: "I plead for justice, fair dealing, and common sense in this matter."

For whom is he pleading? Is it for the sick person? Then it seems to me he should recognize the fact that the welfare of the community depends upon that of the individual, and that laws made by the community and regulating individual action are presumably made for the good of the community, and are, therefore, not infringements upon personal liberty. Whether we have laws forbidding self-torture I do not know, but we certainly would have if it became a common practice. We do have laws forbidding suicide. We do have laws protecting children against maltreatment and neglect even at the hands of their own parents, who may think they are exercising their best judgment in that very maltreatment.

Are these laws unwarranted? Does he plead for the faith healer? Then he throws down the bars and abolishes all restriction and regulation by law of the healing art, and invites any and all who will to come in and practise upon the sick without qualification either of education or experience. He would open the door to all the charlatanism, mummery, and quackery that cursed the Middle Ages, and that still curse China, India, and darkest Africa.

I do not mean by this to place Christian Science and faith cure in the same category as the preceding, for I, too, believe they have a place of usefulness to fill, especially in certain conditions classed as "neuroses" and "psychoses," and that they are, in the main, practised by well-meaning and even disinterested persons. More than this, I believe that very many among the more intelligent of Dr. Steele's "drug doctors" are applying the real principle involved—the training of the will-power, call it by whatever name you wish—to many of their cases, and with marked benefit.

This, however, is no reason why a person who has never studied anatomy or pathology, and who claims that there is no such thing as appendicitis, should be allowed to treat people sick unto death with what we poor misguided mortals believe to be disease. That is decidedly against the best interests of the community, not to say of the poor individual.

No set of laws was ever framed which completely accomplished the end in view. Those regulating the profession of the physician are lax enough, we all know, and recognize the right to practise of many who are absolutely unqualified to do so, and we must constantly strive for better ones. They do, however, compel a man at least to show evidence of having tried to learn something about the human body in conditions of health and disease, and a man who has done that is presumably better qualified to practise the art of healing than one who has not.

"The argument for compelling a man to have a drug-doctor" is not "that he may die"—no, sir!—he may do that anyway—but that his chances for recovery are generally better if he is looked after by one who has devoted some time to the study of sickness; and therefore and thereby the interests of the community at large are better served.

How is it in other walks of life? Is the locomotive or the steamship engine entrusted to the management of any one who applies for a position? No. Human life is too precious a thing to be trifled with. He must first furnish evidence that he has some knowledge of the machines in question and is reasonably qualified to manage them. The law requires it. How much greater then is the necessity for restriction of those who care for the ills of humanity!

I am sure Dr. Steele cannot wish to throw down the all-too-feeble barriers that guard our sacred calling, but that he, with all thinking men in the profession, must earnestly wish and strive for the strengthening of them, to the betterment of the quality and ability of those who obtain the legal right to practise, and to the lasting benefit of society.

Philip F. Rogers, M.D.

1130 State Street, Milwaukee, Wis.

---

To the Editor of the Medical Record.

Sir: The article under the above title written by Dr. N. C. Steele, of Chattanooga, Tenn., has attracted my attention by the brilliancy with which Dr. Steele defends the "faith healers," or "Christian Scientists," and by his pleading for justice, fair dealing, and common sense in this matter. I shall set justice and fair dealing aside (only for a while), and consider the question with pure common sense.

We live at the close of the nineteenth century, a time in which medical science is at the summit of its progress, the causes and the pathology of the majority of diseases are accurately known, the action of drugs is thoroughly investigated and settled—a time when the germ theory is accepted by the most scientific men. A clear mind and common sense can by no means understand how a man of learning can defend a theory that is based on the people's superstition, a theory that pretends to cure the gravest diseases by—by what? We positively know that the typhoid, tubercle, and anthrax bacilli cannot be destroyed even by the most devoted prayer (though that prayer possesses antiseptic properties).

We also know that all the sciences having only the slightest foundation are studied and lectured upon by the most prominent men of our time. Ancient mythology, though only fanciful to the mind, has been studied by a number of learned men, and thousands of books are written on this subject. But what of the "Christian Science" as concerned in the treatment of diseases? Has any man of learning ever advocated this theory? Has any university or medical school taken up this subject as a branch of its general teaching? As the case is not so, and as "faith cure," or "science," is embedded in the minds of a few fanatics only, common sense must and does condemn it.

As regards "justice and fair dealing," how shall we extend justice to people fleeing from it? Do the "Christian healers" preach their doctrine openly, and submit it to our judgment? No. We are aware of their real existence only by the fatal outcome of a case that was treated, or rather mistreated, by one of their members. It is true that "drug-doctors" also lose cases, and that the law cannot compel a person to be treated by a physician when he prefers a "faith healer." But a physician losing a patient, because he could not combat the fatal disease even by the most desperate efforts, surely saves the lives of numbers of others. But what means does a "faith healer" employ to prevent a death? How many people with slight affections were crippled or led to speedy death by their ignorance? Therefore, when a death is caused by their mistreatment, which very often happens, the outcry must be great, in order to warn others; and though the law cannot compel a person to use a "drug-doctor," it can and shall under heavy penalty compel the "faith healers" to give up the practice of their theory, and by doing so the people will recognize and avoid that fraud; the public will be safe, and the "faith healers," by engaging in an honest employment, may yet be beneficial to the community.

M. Gottesman, M.D.

77 Ludlow Street.

## A HISTORICAL CORRECTION IN CONNECTION WITH THE NAME, "KOPLIK'S EARLY SYMPTOM OF MEASLES."

To the Editor of the Medical Record.

Sir: In the Medical Record of the year 1898, No. 1,431, the well-known American pædiatrist, Koplik, described an early symptom of measles, under the title of "A New Diagnostic Sign of Measles." It consists in the appearance of minute bluish-white specks on a bright red ground. These spots are found on the mucous membrane of the cheeks and lips, twenty-four to forty-eight hours before the breaking out of the exanthema, and can be seen only with a strong light. This symptom was soon verified and confirmed on all sides, and earned for the author's discovery the name of "Koplik's early symptom." Every one indeed wondered how such a remarkable appearance could have remained so long undiscovered. I among others was so surprised at its being overlooked, that I was led to look through the literature of the subject, with, in short, the result that in the widely known "Compendium of Pathology and Therapy," written by H. Nothnagel, I found, under the heading of the "Acute Exanthemata," by Jürgensen, a description of the early course of the enanthema and exanthema in measles by the Danish physician, M. Flindt. I extract the following from Jürgensen's work:

"The best description is given by Dr. M. Flindt,[1] and deserves to be exhumed out of the records of the Danish 'Sundhedscollegium.'"

"Second day of fever: A spotted exanthema may be seen on the anterior surface of the soft palate, and on the mucous membrane of cheeks and lips. This shows quite a remarkable appearance due to the numerous minute, bluish-white, shining, and apparently vesicular points which lie in the centre of small red spots, and are arranged in irregular groups. One can feel as well as see the small vesicles projecting out above their surroundings. A similar miliary formation is to be seen on the palpebral conjunctiva.

"Third day of fever: Similarly grouped spots with vesicles are visible on the buccal mucous membrane, especially on that part of it lying opposite to the space between the upper and lower back teeth. At this stage the skin eruption first makes its appearance."

The above is a translation of the original. I wish merely to add, that the first writer was more exact in his observations, in that he palpated the vesicles and described the conjunctival appearances, which Koplik, so far as I am aware, has not mentioned. I may also mention that the time of the appearance of this symptom, namely, before the rash, was defined by Flindt in the year 1880.

Dr. Siegfried Weiss,
*Assistant Physician, Carolina Children's Hospital, Vienna.*

Vienna, September 20, 1899.

---

**Treatment of Tetanus.**—In the treatment of tetanus, prevention is naturally the first point, and as tetanus in aseptic wounds is quite unknown, it is clear that strict purification of wounds likely to be infected with the tetanus bacillus must be carried out. Hence in all cases where a wound is soiled with earth and where lacerated wounds have occurred from falls in stables, gardens, and so forth, the wound must be very thoroughy purified, a nail-brush being used to scrub away earth and the whole wound thoroughly sponged out with undiluted carbolic acid.—Cheyne and Burghard, "A Manual of Surgical Treatment."

[1] Sundhedscollegiets Aarsberetning for 1880. Nothnagel: "Spec. Path. und Therapie," Exantheme, S. 92.

## Medical Items.

**The Causation of Night Terrors.**—Dr. Little, in an article in the *British Medical Journal* of August 19, 1899, expresses the opinion that night terrors are, in the great majority of cases, caused by disorders productive of moderate but prolonged dyspnœa. A preponderating number of cases are found in rheumatic subjects with early heart disease. A considerable proportion of cases are due to obstruction of the nasal cavities and fauces. Digestive disturbances do not play the important part in causation that is often assigned to them. The evidence for their causal connection with epilepsy or allied neuroses is scanty. The attacks occur in the subconscious stage of early sleep, and are confined to young children under puberty.

**A Vegetarian King.**—The king of Italy, according to an English journal, is a vegetarian, and lives entirely on vegetables and fruits. The doctors have also forbidden him to drink coffee, so his beverage is claret well diluted with water. The king never feels so well as when his fare is bread, potatoes, and oranges, although peaches are his favorite food. The queen has made repeated attempts to become a vegetarian, but finally has given up in despair, being fond of a generous diet.

**A Pediatric Physician at King's College Hospital.**—The London correspondent of *The Therapeutic Gazette* says that Kings College Hospital, London, has just appointed a special physician for diseases of children. In America and in several continental nations, this would hardly seem worthy of comment, but as a fact this is the first appointment of the kind in a general medical school that has been made at any general hospital in Great Britain.

**Physicians in Germany.**—The statistical office has just published returns relative to medical qualifications in Germany, which show that 1,314 candidates became qualified in 1898. Of this number 20 were foreigners, including 8 Russians, 4 Swiss, 3 Dutchmen, 2 South Americans, 1 Englishman, 1 Mexican, and 1 African. The total duration of medical study varied considerably with different candidates; 936 studied for nine semesters, 158 for ten semesters, and 211 for eleven semesters and upward.—*The Lancet.*

**A Vegetarian Sanatorium in Great Britain.**—On the borders of Epping Forest, a few miles from London, is a sanatorium at which the fresh-air treatment is pursued together with strict dieting, the consumption of flesh, fish, or fowl being absolutely prohibited. The results of this system, it is claimed, are most beneficial to the patients, especially in cases of tuberculosis, but cases of cancer (in the early stages) are dealt with on the lines of the experiments tried by the celebrated Abernethy many years ago. Patients also suffering from chronic dyspepsia, from debility and wasting are admitted. The hospital was opened in 1895, and has proved so successful that it frequently happens that applications for admission have to be refused owing to lack of room.

**The Hygiene of Railways.**—For a long time those concerned with the question of public health in France, as in other countries, have been complaining of the carelessness of railway companies in taking sanitary precautions to guard the health of their patrons. The minister of public works in France has, at the instance of the committee of hygiene, issued a circular in which it is suggested to the railway companies that they

should cause the floors of carriages and waiting-rooms to be washed every day with some antiseptic solution, and that a notice should be posted in carriages and other public places, as is the custom in all the chief towns, forbidding people to spit on the floor. The railway companies, however, have ignored the circular, and owing to numerous representations in the medical journals the minister has just sent to the railway companies a more pressing circular than the first, and has organized a system of surveillance in order to ascertain whether his instructions are properly carried out.

**Several Quivers Full.**—Queen Victoria has seventy-one direct descendants. The queen has seven sons and daughters living, thirty-three grandchildren, and thirty-one great grandchildren.

**Poisoned Bullets Required by the Boers.**—In a bi-lingual journal published in an Orange Free State town appeared recently the following advertisement: "War! War! Wanted two genuine Bushmen, woman and man, for the purpose of making their well-known poison; salary £10 ($50) per month. The above-named poison must be suitable for the immersion of our bullets, as I think it would be very unfortunate that our enemies should be shot with bullets not so immersed."

**Teaching University for London.**—Sir Philip Magnus, speaking at the meeting of the British Association concerning the proposed university for London, said: "A feature of the new university will be the faculties. These will be at first eight in number. They will consist of the professors and teachers interested in each great branch of learning. To the older faculties of law, medicine, theology, arts, and music will be added the newer faculty of science and the newest faculties of economics and engineering."

**Effect of Emotion on the Liver.**—Jonathan Hutchinson says that it has often struck him that we may perhaps infer from what is so easily observed in the case of the salivary glands as to what may not improbably be possible in that of such glands as the pancreas and even the liver itself. We know how easily certain kinds of emotion may cause the mouth to become dry and the salivary glands to cease their secretion for a time. We know also that in some persons the arrest of secretion may be permanent, and that probably in many more a partial arrest may become more or less habitual to the individual. If similar occurrences are possible in the liver, we have an easy explanation of the phenomena of bilious disturbances with or without jaundice.

**Sudden Changing of Color of Hair.**—M. Schmidt, of Frankfort, reports in *Virchow's Archiv*, vol. 156, No. 1, 1899, a case of sudden turning of the hair to gray. The patient was a laborer thirty-six years of age, who at the time was suffering from some affection of the neck. His hair showed two white patches, one in the middle line of the head, the other over the right ear. Eight years previously the patient had had a severe mental shock while on a railroad journey, and it was noted by his friends and relatives that these patches appeared almost immediately after. The possibility of its having been a congenital or gradually acquired defect, covered by hair dye, as has frequently been shown, seemed remote.

**Tallest Children Born in Summer.**—According to Combe, boys born in the months of September, October, November, December, January, and February are not so tall as those born in other months. Those born in November are the shortest. Those born in July are the tallest. Girls, according to the same authority, born in December, January, February, March, April, and May show a less length of body than those born in the remaining months. Those born from June to November are taller, but the tallest are born in August. The investigations of Wahl, in Denmark, and Wretlind, in Gothenburg, and especially those of Malling-Hausen in Copenhagen, on the deaf show that the length of body of boys from March till August increases greatly, but very little from September to February. Dr. Macdonald attributes this fact to some extent to economic conditions, for a child born in summer has generally better food and air. A large number of parents are poor, and in winter they are forced to economize on account of the expense of heating. They generally live also in small and ill-ventilated rooms. The influence of such conditions on a very young child would be much more detrimental than when the child is older and better able to resist unfavorable surroundings.—Dr. Macdonald, in *Child Study*.

**Inoculation for Rabies.**—At the Pasteur Institute in Paris, 1,465 persons were treated in 1898, and all but three were cured. For the thirteen years from the foundation of the Institute to the end of the year 1898, 13,181 persons were treated in Paris, and out of this number only 99 died.—*Scientific American.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 14, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |

### STATE CARE OF CONSUMPTIVES, WITH AN ACCOUNT OF THE FIRST STATE HOSPITAL FOR TUBERCULOSIS IN THIS COUNTRY.[1]

BY ALFRED MEYER, M.D.,

NEW YORK.

To a medical man who began his professional work twenty or more years ago, there are few changes of professional opinion more gratifying than the one involving the prognosis of pulmonary consumption. The hopelessness with which these cases were generally regarded at that period led either to an excess of empirical medication, or to a therapeutic nihilism which more or less resignedly (according to whether it was the doctor or the patient) awaited the fatal end. Andral[2] said: "No fact demonstrates that phthisis has ever been cured, for it is not art which operates in the cicatrization of caverns," etc. Strange to say, Laennec's view was that phthisis of the first degree was incurable, but that if the case had advanced to the formation of a cavity there was a possibility of recovery by cicatrization. In 1870 Niemeyer wrote in his text-book of practical medicine: "It follows from what has been said, that death is the most frequent result of all forms of pulmonary consumption, and that it is the sole termination of tuberculosis, but that, in the forms of the malady which are dependent upon pneumonia, an improvement and approximative recovery are not so rare an occurrence as is usually supposed." Even the concluding and more favorable part of this opinion appears "to damn the prognosis with faint praise."

In the history of medicine there were not wanting voices raised energetically from time to time in favor of a more active outdoor life in the treatment of this disease. Burton-Fanning[3] mentions even Aretæus, Hippocrates, Celsus, and Galen among the number. But until recently the medical profession as a whole took a pessimistic view of the disease and was slow to appreciate at their full value the benefits of the outdoor treatment—*i.e.*, the outdoor treatment under daily medical supervision—the outdoor sanatorium treatment.

It is nearly fifty years since Dr. Brehmer, of Goerbersdorf (then a young medical man), published his book upon the curability of pulmonary consumption and set to work to give his ideas practical shape and practical results, in the teeth of much hostile criticism. And these results were before the medical world many years before they were estimated at their true worth. This appears all the stranger when we remember that during all these years of slow evolution of opinion regarding prognosis, confirmatory evidence of the curability of the disease was already at hand from the post-mortem table—overwhelming evidence accumulated by innumerable pathologists the world over of healed tuberculous lesions in the lungs of people who had died of other diseases. The value of this evidence was made almost irrefutable by the discovery of the tubercle bacillus, which simplified the diagnosis both ante mortem and post mortem, and removed the long-standing confusion and conflict in classification. These various factors have gradually moulded professional opinion not only to the importance of an early recognition of the disease, but also to the true value of the sanatorium treatment, and of the principles underlying it. And now the end of our century witnesses all over the world an intensity of interest and earnestness of purpose in the prophylaxis and cure of this disease that would scarcely have been believed possible a quarter of a century ago. The spirit of pessimism has been replaced by one of reasoning and reasonable optimism. The efforts of individuals for the relief and suppression of the disease, especially among the poor, have been supplemented by the efforts of societies and of organized bodies of professional and lay men, so that there is scarcely a country in Europe in which sanatoria for rich and poor do not exist; and in some countries, notably in Germany and France, their number is rapidly increasing. In the Orient, Japan was preparing to erect a sanatorium under the patronage of H. I. M. the Empress so long ago as 1897.[4]

In our own country excellent preliminary work has been done in the eastern States by Trudeau, Loomis, Bowditch, and by institutions like the country sanatarium of the Montefiore Home, the Seton, Gabriel, and de Peyster Sanatoria, the St. Joseph's Hospital in New York, the Brooklyn Home for Consumptives, and the Philadelphia Home for Consumptives. Finally the establishment of the Massachusetts State Hospital for Consumptive and Tuberculous Patients marks an era in the fight against the disease in the United States—not because of the additional number of invalid poor thereby provided for, but because it recognizès for the first time, distinctly and unequivocally, the principle of State aid for this class of people, and opens up a promising vista of imitators in all the States of the Union. Just as forty years ago in the movement for the emancipation of the slaves this New England State was in the forefront of the fight, so to-day, in the quickened movement against tuberculosis, Massachusetts is again leading the way—an example to her sister States in well-directed, public-spirited, humanitarian work.

In view of the fact that a bill was before the New York legislature last winter to appropriate $200,000 for the establishment of a State sanatorium in the Adirondacks, and that this bill, or a similar one, will be re-introduced next session, it may be of interest to the members of this section to learn more definitely what has been accomplished in Massachusetts, and how it was done. A recent visit to Rutland, where the Massachusetts State Hospital for Tuberculosis is located, has given the writer an opportunity to see for himself what is being done. He is indebted to Judge Hammond, of Northampton, for certain data of the earlier steps.

After the preliminary agitation the movement in Massachusetts finally took shape in 1895 by the appointment by the legislature of a board of trustees of five members, and an appropriation of $150,000. The first step of the board after organization was to send a circular letter of inquiry to all the registered physicians of the State. Much valuable advice was thus obtained and the judgment of the profession as a whole ascertained upon a number of points. The next step was the selection of Rutland, near Worcester, as the site. It is an interesting fact that the site chosen is the exact geographical centre of the State; it has an elevation of eleven hundred and sixty feet above the sea, sheltered by a hill to the north which is about one hundred feet higher, and included in the hospital grounds are about two hundred acres of land. The plans of a Boston architect were accepted; they called for detached wards one story high, alternately long and short, separated sufficiently for the best sunlight and air, and connected only by a convenient corridor. The hospital was opened October 1, 1898, and the first patient was received on October 3, 1898. At the date of my visit early in April, 1899, the institution was full, and contained one hundred and seventy-five patients, male and female. The superintendent, Dr. Marcley, was absent, but I was most cordially received into the hospital family by Drs. Butler and Dunham. The wards are arranged like the spokes of a wheel, all leading at their northern end to a long corridor which connects them all, forming, as it were, the rim or tire of the wheel. At their southern end they are provided with a large glass-covered solarium and outside of this with a broad veranda having three different exposures, and giving excellent opportunity for the out-door rest cure. The central and present administration building is two stories high and separates the male wards from the female wards. On the exterior the buildings are all finished in Portland cement (slap-dash finish), and above each ceiling is a ventilating space connecting with a series of openings under the eaves. All corners are rounded, and the corridor has no stairs, but follows the natural grade; both of which details prevent the accumulation of dust and thus add to the sanitary perfection of the buildings. Each long ward has twenty-two beds, and there are besides five rooms with one or two beds each, for the accommodation and isolation of cases developing complications. The lighting is by electricity throughout, the heating by both steam and hot air. A large open fireplace and chimney in the centre of each ward rather serves the purpose of ventilation than of heating. The hospital management is in charge of a superintendent who is a medical man and a salaried officer. The medical care of the patients devolves upon two attending physicians, Drs. Bowditch and Clapp, of Boston, representing the two schools of medicine—both salaried officers. Each one visits the institution once a week and also has a stated office hour once a week in Boston for the examination of patients for admission.

Fig. 1.—Long Ward.

Residing at the hospital and representing them in their absence are the two house physicians, who receive their appointment for one year and are unsalaried. Patients (or their counties) pay $5 per week, and have their choice of either the allopathic or homœopathic division.

The general routine of the establishment is very much on the order of other similar institutions. Each patient is furnished with a note-book in which he enters the number of hours spent out of doors daily and condition of sleep, bowels, and appetite. In addition each patient is encouraged to buy his own clinical thermometer, and to keep a record of his temperature. Every patient is furnished with a sanitary pasteboard sputum cup for indoor use, and these together with their expectoration are burned daily; when away from the institution, he expectorates into pieces of Japanese paper, which he puts into a self-closing rubber pouch (old-fashioned tobacco pouch) carried in the pocket. Napkins of Japanese paper are used at table, and are burned after use. Three hearty meals and three light ones are served daily.

The out-door life of the patients during the winter has been encouraged by permitting the hardier ones to fell dead timber on the State lands adjoining the institution, and to burn this at three winter camps built by the patients themselves. The patients gather about their winter camp-fires like veritable backwoodsmen, spin their yarns, smoke a sly pipe, and grow young in spirit and in body. One of these camps, "Camp Welcome," may serve as illustration. It is merely an open space among the hemlock trees, screened from the wind on all sides by woven hemlock boughs, the handiwork of the patients. Alongside these screens are ranged plain board benches for the patients to sit on, and in the centre, over the fireplace, there is a piece of old discarded ventilating pipe to improve the draught of the fire. The healthful exhilaration of these winter camps has made them a great attraction to the patients and a great adjuvant in the treatment of their disease.

There is no special provision for hydrotherapy, cabinet treatment, or the employment of the Roentgen rays for diagnostic purposes. By the system of ventilation in vogue, which is under the supervision of trained nurses, the patients are soon accustomed to sleep with windows wide open on the leeward side all

night; and, as a matter of fact, the temperature of the wards, day and night, has seldom been above 40° F. all winter. There are no male nurses. In the daytime there is one female nurse assigned to each ward and adjacent private rooms, being one attendant for about thirty-two patients. At night there is one nurse each for the entire male and female services respectively, a total of about ninety patients each. This is undoubtedly an insufficient number of nurses, a fact very well recognized by the management, but not remedied, from motives of economy. Patients who are able will be employed to do light work: grading and gardening. There is no special amusement hall, but there is a small library, one of the inmates acting as librarian, and once a week there is an entertainment in the way of music, lecture, or a reading by volunteers from different parts of the State. The general atmosphere among the patients is one of cheerfulness and hopefulness, a natural consequence of the adoption by this institution of that fundamental idea in the sanatorium treatment of phthisis, the absolute separation of the hopeless cases from the hopeful ones. And this means, not their admission to a separate floor or a separate wing, but their entire expulsion from this institution. Cases whose prognosis was sufficiently favorable to secure their admission are discharged if they do not show improvement within four or six weeks—the improvement being gauged by the weight, temperature, dyspnœa, cough, expectoration, and general strength. The interesting fact was noted that scarcely any coughing was going on—a fact frequently observed at similar institutions, and often commented upon by those who have had occasion to visit them. The writer confesses to being almost the only one whom he heard cough during a stay of nearly twenty-four hours.

In the first six months of its existence two hundred and twenty-four patients had already availed themselves of its benefits, a very large number of whom had been improved by an average stay of four months only.

Roughly sketched, this is what has been accomplished in the direction of State care of the consumptive poor by the State of Massachusetts. Is there any good reason why the State of New York should not accomplish as much as her sister State? It may have been said that there were theoretical objections against such institutions in our country—that they savored too much of a "paternal" system of government, and that the solution of the tuberculosis problem should be left to the individual citizens or to organizations formed by them. But, with a few striking exceptions, we have waited in vain for such united efforts, and these few exceptions have made more striking the inadequacy of our provision to deal with this great problem—a problem made still more difficult by the tendency to exclude cases of tuberculosis from the general hospitals, which has followed the modern view of its infectiousness.

Now, when analyzed, what is the value of the theoretical objection to State care? "The State exists as a commonwealth by virtue of its constitution, and all State authorities, legislative, executive, and judicial, are the creatures of, and subject to, the State constitution."[1] Now there is probably no State constitution in the Union that does not contain provisions relating to State hospitals, as well as to State prisons. Nor is it clear why the State should not control its helpless sick, as well as its criminal classes, in the case of tuberculosis, for its own protection as well as for the interest

Fig. 2.—Patients Out in the Snow.

[1] Bryce "The American Commonwealth," vol. i., p. 420.

of the sufferers. In fact, after a study of the form of government of every State in the Union, Bryce[1] says: "A spirit of humanity and tenderness for suffering,

Fig. 3.—Patients Tramping through the Woods.

very characteristic of the American people, appears in the directions which many constitutions contain for the establishment of charitable and reformatory institutions." State care of the poor consumptive would not belie one of the great merits of the American form of government, namely, "that it relies very little on officials and arms them with little power of arbitrary interference," because it would devolve "functions that serve to aid the individual and the community rather than to interfere with or supersede the action of private enterprise."[2] In the case of the State care of the insane this step was the natural outcome of the county care, to the extent at least that there was the example or precedent of care by the smaller unit of the body politic. In respect of State care of the consumptive the situation is somewhat different. It would be on a par with the State provision for the epileptic, in that no separate provision had been made by the constituted authorities for either type of sufferers; with this important difference, however, that while there were supposed to be about twelve thousand epileptics in the State at the time of the agitation for their State care, there are upward of thirteen thousand deaths from consumption annually in this State. This is a larger number than all the deaths from scarlet fever, measles, whooping-cough, and diphtheria combined. It is just this enormity of the problem that seems all the more to justify State aid. But even granted that the theoretical objection be valid, must we not in all fairness ask ourselves whether they weigh in the balance against the good to be obtained?

And for that matter did not the theoretical objection apply with equal force to our sister State? And if the practical blessings, direct or indirect, to be expected for all citizens in that State outweighed the theoretical objections, may they not reasonably be presumed to do so in the State of New York? Where is the fundamental difference, either of people or of policy?

As for the practical objections, what are they? Mainly those of expense—the same argument that was raised effectually for some years against the State care of the insane. In the year 1889 one of the great New York dailies said of this matter: "In the interest of the good name of the State of New York it is greatly to be hoped that the present legislature will not again treat this question, purely one of humanity, as a matter of dollars and cents." These words are just as applicable to-day to the question of State care of consumptives, and additional force is lent to the argument by the vastly greater number of people whose interest, nay, whose very life, is at stake.

The bill before the legislature last winter to appropriate $200,000 for a State sanatorium in the Adirondacks, though acceptable in principle to senators and assemblymen generally, was not reported favorably by the finance committee because of the expense involved and a desire to economize. Regarding this phase of the question permit me to quote what was said by a medical paper (whose identity I am at the moment unable to recall) when a similar objection was urged against the Massachusetts bill: "When the worthy but poor consumptive is taken in time to an institution where his chances of recovery are still good, he will have little chance to infect the other members of the family, and he is likely to return, after a relatively short sojourn, restored to health and hygienically educated, ready to become again a bread-winner and a supporter of his family. Now, the maintenance of this patient in a municipal (or State) sanatorium for from three to six months or longer, during the earlier stages of the disease, will cost the commonwealth no more than if he

Fig. 4.—Outdoor Rest Cure.

[1] Bryce: *Loc. cit.*, p. 443.
[2] Bryce: *Loc. cit.*, vol. ii., p. 467.

had been taken to the general hospital for perhaps the same period of time, but in a much farther advanced and more hopeless state of his disease. If the family were absolutely destitute, the members would have to be supported by the municipality, whether the head of the family were in the sanatorium or general hospital. But since when treated in time and in a special institution he has twenty-five to thirty-five more chances of getting well, the likelihood of the community being obliged to support a widow and several orphans has thus also been reduced by nearly one-third."

In certain quarters there has been a tendency to lay too much stress upon the gradual but steady diminution in the death rate from pulmonary consumption in various parts of the world. After a study of the vital statistics of England and Wales, Ransome[1] concludes that "if phthisis diminishes there at the same rate as it did during the last fifty-eight years, during another thirty years it will have entirely disappeared by the end of that period." Even accepting this as a truthful horoscope for our country and countrymen, it is of no more practical value to us to-day than would be the promise of a generous meal a year hence to the starving beggar of to-day—with this difference, perhaps, that such calculations add another element of hopefulness to a situation so long regarded as hopeless, and give renewed encouragement to the profession and the world.

It ill becomes us to sit down with our hands in our laps and to await this millennium. Even if we are too late to be leaders in this great modern movement let us at least be good followers, profiting by the example and experience of others, and ranging ourselves alongside the great European countries in this fight of humanity for humanity.

1 Madison Avenue.

## THE SPHERE OF DRAINAGE IN SURGERY OF THE APPENDIX.

By WILLIAM STEVENSON MacLAREN, M.D.,

LITCHFIELD, CONN.

The sphere of drainage in the surgery of the appendix may, I believe, be well defined, and is, I also believe, very limited.

For convenience in discussion, cases of suppuration about the appendix may be divided into two classes; the first class comprises those cases in which the abscess is localized, being shut off from the general cavity by adhesions; the second includes all those more serious cases in which the pus has entered the general abdominal cavity and caused greater or less inflammation.

Cases of the first class are simple abscesses and should be treated like abscesses of any other region. In these cases drainage is a perfectly proper, though sometimes unnecessary procedure.

The second class, however, are totally different in all their conditions, and there is no more propriety in treating them like abscesses than there would be in giving ulcer of the stomach treatment that would be proper for ulcer of the leg.

My reasons for feeling so strongly opposed to drainage in these cases are two. In the first place drainage, properly speaking, in them is an impossibility. In the second place, I am opposed to it because there is another procedure which is feasible, more rational, and must give better results.

Attempts at drainage usually take one of two forms: the glass tube or gauze strips. We all know how quickly a foreign body in the abdomen becomes shut in by adhesions. During my service as interne at Bellevue Hospital, some years ago, when drainage was more fashionable than it is at present, I watched this phase of the question very closely, and I have seen isolation complete at the end of twelve hours. If this occurs in those cases in which we are able to perform an autopsy, how much more certain to occur it must be in the body of a person having sufficient vitality to recover! Not only does the drain accomplish no good purpose, but it is in itself a factor on the wrong side. It cannot help recovery, but directly militates against it, for it irritates a surface already inflamed.

That this irritation is a fact is proven by comparing the dead-house findings in undrained abdominal sections with the histories of those cases that result in recovery in spite of the drainage tube. When section has been performed for simple ovariotomy, and death ensues from causes other than inflammation of the peritoneum, we do not expect to find serum in the pelvic cavity. If, however, a glass tube is used, the house surgeon, with his little syringe, is able to draw from the small pocket thus formed from two drachms to half an ounce of bloody serum every two hours for two or three days, if the visiting surgeon deems it wise to keep the seton in place for so long a time. If gauze strips are used, the irritation caused increases directly in proportion to the number of strips employed.

Why should a man who, in operating for a wound of a viscus in which infection is feared, introduces strips of gauze to encourage the formation of adhesions shutting off this region from the general cavity, expect that gauze introduced for purposes of drainage will not become isolated with equal promptness? The only good which may be rationally hoped for from drains used in this way is that among the many lines of irritation there may be one which passes close to a pocket in which pus is forming, and that this pus may break through into the line of the drain. This is a possibility; if, however, no drains had been employed, and such a pocket had formed, it would be equally possible for the pus to find its way into a hollow viscus, and the certainty of drainage irritation would be obviated.

The procedure which I would urge as a substitute for drainage is the same that has been recommended by Wiggin for a variety of other purposes, and is its exact opposite. I refer to leaving the abdomen filled with saline solution. We all, I believe, admit that the peritoneum has to a certain degree the ability to resist infection. I believe this resisting-power is enormously increased by the presence of the fluid. The reasoning which brings me to such a belief is this: In the first place, let us suppose that in a given case, after the peritoneum has been cleansed as thoroughly as possible, there is a small corner, an inch square, which is still infected; let us call the amount of this particular variety of infection, which a square inch of peritoneum can destroy, one; but let us further suppose that the actual amount of infection on the square inch in this case is equal to three. It is evident that if two-thirds of the total amount of infecting material could be removed from the surface, and prevented from multiplying while the one-third was being destroyed, and then, a little at a time, brought again in contact with it, the entire amount of that infecting material could be destroyed by the one inch of peritoneum. This is one thing which the saline solution accomplishes. If an amount of fluid is placed in the peritoneal cavity, which will require four or five days for its absorption, it can readily be seen that the infecting material, which, instead of lying in contact with the peritoneum, is diffused throughout the mass of the fluid, will be returned, little by little, to the surface during the absorption of that fluid; and the original

[1] Weber-Parkes Prize Essay, 1897.

amount of infecting material will not be markedly increased, as saline solution is not a culture medium.

In the second place, taking the same supposititious case, in which the amount of infecting material that may be destroyed by an inch of peritoneum is one, but the amount present is three, if we could take that infecting material and, instead of leaving it in contact with one inch of peritoneum, could spread it over three inches or more, we would by this means again render possible the destruction of all the infecting material. This is another thing which the saline solution definitely accomplishes. The infecting material, instead of being left in contact with a small area of peritoneum, is diluted and brought in contact with the entire lining of the peritoneal cavity.

To demonstrate that this procedure, which seems to me so sound in theory, may also lay some claim to soundness in practice, I would briefly mention two cases. The first of these came under my own observation; for the notes regarding the second I am indebted to Dr. W. L. Platt, of Torrington, Conn.

On March 29, 1898, Dr. Elias Pratt, of Torrington, was called to see William W——, aged sixteen years, who gave the following history: There have been several attacks of pain in the right iliac region. The last of these occurred in July, 1897, at which time he was ill for three days. No physician was called. Since this time there have been occasional ill-defined colicky pains. The present illness began during the night just passed. The patient was kept awake by colicky pains referred to the right iliac region. There was some vomiting. Examination disclosed slight tenderness at McBurney's point. The pulse was 65; temperature, 99° F.

March 30th: Pulse, 70; temperature, 99.5° F. There was slight pain, and the tenderness was increased. The bowels moved during the preceding night. 11 A.M.: There was chill accompanied by vomiting. Pulse, 85; temperature, 101.5° F. 4 P.M.: Pulse, 100, temperature, 102° F. There was no further vomiting; the pain was not marked. The tenderness was increasing. 9 P.M.: Pulse, 90; temperature, 101.5° F. There was perceptible resistance on palpation; the percussion note was dull.

March 31st, 6 A.M.: Pulse, 95; temperature, 100.5° F.; the condition was much the same as the previous night, except that resistance was increased. At about 11 A.M. on this day I saw the case with Dr. Pratt, and, on his agreeing with me as to the need of immediate surgical interference, I decided to operate as soon as preparations could be made. By 2 P.M. the pulse had reached 110, temperature, 102° F.

The operation was performed with Dr. Pratt's assistance at 4 P.M. Under ether anæsthesia the abdomen was opened by a three-inch incision parallel with Poupart's ligament. On opening the peritoneum there was an immediate escape of extremely foul-smelling pus and a small quantity of gas. The appendix was readily found in a pocket opening freely into the general abdominal cavity. It was about two and a half inches in length and gangrenous at its extremity. Some difficulty attended the removal, owing to lack of assistants, extreme rigidity of the abdominal muscles, and a broad, short mesocolon. The appendix was partially surrounded by a fold of omentum, which, as it was in a sloughing condition, was removed. The remaining adhesions were broken up, and the peritoneal cavity was washed as thoroughly as possible with decinormal salt solution, by means of a long glass tube used as an irrigator nozzle, and introduced into the lower part of the abdomen and pelvis. Owing to the rigidity of the muscles I feared that the washing through the original incision could not be thorough, and for this reason made a second opening parallel with and to the left of the median line. Through this second opening I was able to remove about an ounce of pus, which would otherwise have remained between the bladder and rectum. Eight ounces of the peroxide of hydrogen, full strength, were poured into the abdomen and allowed to remain for several minutes. The washing was then repeated. The first incision was then closed; the abdomen was filled with saline solution, and the second incision was closed, leaving no opening for drainage. The coils of intestine in the upper part of the abdomen had appeared normal; those in the lower part were congested and dotted with a few fine flakes of fibrin. At 9 P.M. on this day the pulse was 130; temperature, 102° F.

April 1st, 7 A.M.: pulse, 124; temperature, 101.2. 7 P.M.: Pulse, 114; temperature, 101.8°.

April 2d, 9 A.M.: Pulse, 74; temperature, 99.2°. 10 P.M.: Pulse, 78; temperature, 99.8°.

After this the pulse remained normal and the temperature never reached 100° F. The bowels were moved with Seidlitz powder on the fourth day.

The second case occurred in the practice of Dr. W. L. Platt, of Torrington. In February, 1899, he was called to see Daniel C——, who presented signs of appendicitis. These signs became steadily more marked, and three days later Dr. Platt decided to operate. When the abdomen was opened the appendix was found to be perforated and was removed. The adhesions were few. There was an abundance of pus in the general cavity. The intestines were found to be inflamed and covered with an exudate, which could be washed off only with difficulty. By the advice of Dr. Pratt, who was assisting him, he employed the technique which had proved successful in my case. The peritoneal cavity was washed thoroughly; the peroxide was used, and the washing was repeated; the abdomen was filled with saline solution and closed tight.

This patient, just before the operation, had a pulse of 125, temperature, 103.5° F. The day following the operation the temperature came down to 100° F., and stayed down until three days later, when a temperature of 101.5° F. marked the beginning of the formation of a mural abscess. This abscess was opened, and from then on recovery was without event.

Both of these patients are strong, hard-working young men to-day.

These cases, coming together in this way, impress me as being worthy of consideration. They belong to a class of cases in which the prognosis is never any too favorable.

I believe that drainage in these cases is irrational, because it does not drain, and because any foreign body must add to the already existing irritation. Filling the abdomen with saline solution I believe to be rational, because it dilutes the poison which is generated during the few hours immediately following the operation, and vastly increases the area of the peritoneum which is called upon to resist that poison. In this belief I earnestly commend these thoughts to your consideration; feeling confident that, if this method is followed, some of those patients which now almost get well will have the balance tipped in their favor.

---

**Symphyseotomy.**—I can conceive of no possible valid objection to uniting them (the bones) firmly with stout silver wire. . . . Lusk says, "The weak side of symphyseotomy is the imperfection of all methods thus far devised to secure coaptation of the parted surfaces after the operation." I believe that the weak side may be made strong, and that we are entirely wrong in blaming silver wire with bad results due to infection or other causes. The safest of all material to bury is silver, and the safest material to bury it in is bone.—William S. Carr.

## A BRIEF HISTORY OF FIVE CASES OF MASTOIDITIS.[1]

By ROBERT LEWIS, M.D.,
NEW YORK,
INSTRUCTOR IN OTOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

Case I.—On December 29, 1896, De Witt H——, the son of a physician, aged nine years and six months, was taken ill with scarlet fever. On January 2d nasal diphtheria added its complications, and on January 6th the disease was still further complicated by an acute inflammation of the middle ear of the right side. Dr. Albert H. Buck saw the case on January 11th and performed a paracentesis of the right membrana tympani. He ordered douching with a bichloride solution of 1 : 6,000. Two days later, mastoiditis was well marked. Dr. Buck referred the case to me, and I, with the assistance of Drs. Burnett and Strong, opened the mastoid cells in the usual manner. There was marked involvement of the mastoid with considerable pus. Four days later, the lymphatic glands of the neck on the same side became involved in the pyæmic advancement and on the next day had to be opened. They were found to be very necrotic. On the 22d, an inflammation of the left ear set in, and paracentesis of the membrana tympani was done on this side. On the 24th the left mastoid was opened, and a condition similar to that on the right side was found. About the 27th, pericarditis and endocarditis, with mitral regurgitation and aortic obstruction, were discovered to be present. On February 22d the child was sent to his home in the centre of the State, the left ear having entirely healed, and with only a slight discharge from the right. By the middle of March, this latter discharge had also ceased. The boy died on May 10th, having—to quote from a letter of his father's—"for the past two months suffered from cardiac pain and dyspnœa and with a pulse having a range of from 120 to 140." It seems to me that this case, briefly related, well illustrates the fact that the mastoid operation, *per se*, is entirely devoid of danger, for, notwithstanding the marked pyæmic disturbances present, the rapid distribution of poisonous foci from one point to another, and the rapidity with which the tissues succumbed to the influence of the bacterial invasion, and, further, notwithstanding the weakened condition of the boy's physique, after each operation his condition temporarily improved, and the boy eventually recovered from the mastoid operation. The fatal result was due to the fact that such an important organ as the heart became involved.

Case II.—On January 16, 1899, I was asked by Dr. D. M. Marvin, of New York City, to see with him in consultation, A. K— —. From the doctor I obtained the following history: A. K——, a college professor, who was visiting, during the Christmas holidays, friends in New York City, was attacked with acute tonsillitis on December 31, 1898. He was very ill for about five days, when he began to convalesce, and by January 13th he was contemplating returning to his college duties. On that day he was attacked with acute inflammation of the middle ear. Dr. Marvin ordered douching with a warm bichloride solution, and the administration of a saline purge. On the morning of the 15th, the patient arose to dress and suddenly fell over in a faint. Dr. Marvin was called, and upon his arrival found the patient in marked collapse, almost pulseless, and for over two hours the doctor feared he would lose his patient. With strychnine, digitalis, whiskey, and hot saline injections, the heart action was improved. Dr. Marvin could not find anything to account for such marked collapse; all the patient's organs, with the exception of the right ear, seemed to be in a normal condition. The next day he asked Dr. Richard Van Santvoord to see the case with him, and this gentleman also was unable to detect any lesion outside the aural inflammation. (Otorrhœa was now present.)

The next day I saw the case and found the man in a very weak and exhausted condition. The pulse was compressible, intermittent, and about 120. The temperature was 103.2° F. The patient was pale and listless; there was no tenderness, œdema, or redness over the mastoid. The membrana tympana was bulging, especially in the upper posterior quadrant, in which was a small perforation which afforded escape to a purulent discharge. The patient was so weak that we feared even to move him for the purposes of examination; but, as an operation was imperative, we stimulated him with a hot saline injection containing brandy (half an ounce) and gr. $\frac{1}{20}$ of sulphate of strychnine. We also gave him gr. $\frac{1}{4}$ of sulphate of morphine hypodermatically. The operation was performed under rather adverse circumstances, it being found necessary to use lamplight during the latter half of the operation. While this was in progress the ether had to be stopped a number of times, and the patient further stimulated. The cortex of the mastoid was found to be very dense and hard, but when once a way had been chiselled through this a large pneumatic space filled with creamy pus was entered. The bony cell walls were all eroded, and this erosion had extended over the bony covering of the sigmoid sinus, which it was necessary to expose from the bulb to the knee, and the surface of which was found to be covered with exuberant granulations. An opening existed in the tympanic roof, but the overlying dura was found to be healthy, and no granulations of any size were present. After the operation the patient's temperature rose to 106° F. and his pulse to 180. Dr. Marvin kept stimulating him during the night; and during the following week he gradually improved so that at the end of seven days his temperature had fallen to 99° F. and his pulse to 100. Shortly afterward, a phlebitis of the left leg and a perihepatitis set in, and these affections complicated and prevented a rapid convalescence. He was unable to go out before the middle of March. The last time I saw him (about March 30th) I found that the aural lesion had entirely healed. This case seems to be of special interest on account of the absence of marked symptoms; only the bulging of the membrana tympani and the purulent discharge being present. And this absence of decided symptoms is especially remarkable when we take into consideration the rapid invasion of the disease and the extensive erosion of the tissues which occurred. This case, as well as the first, also illustrates how trifling is the shock which is associated with the mastoid operation. Especially is this true of the second case, as the patient had been in marked collapse for a period of forty-eight hours before the operation, and indeed was so weak when the time for this arrived that we feared moving him from the bed to the operating-table. It is true that his temperature rose and his pulse increased in rapidity to an alarming extent after the operation, but in the course of twenty-four hours the temporary shock had passed off.

Case III.—Elizabeth G——, aged thirty years, was seen by me on January 27, 1899, in consultation with Dr. J. H. P. Hodgson. Five weeks before she was taken ill with scarlet fever and two weeks later complained of pain in the right ear. The next morning the membrana tympani ruptured with prompt relief from pain. From that time forward the discharge varied from day to day and was treated by douching with warm antiseptic solutions. Five days ago, pain and œdema developed in the region of the right mastoid process.

[1] Read at the thirty-second annual meeting of the American Otological Society, at New London, Conn., July 18, 1899.

On examining the ear I found, besides the marked tenderness over the mastoid process and the œdema, decided bulging of the membrana tympani, and a drooping of the upper posterior wall of the cutaneous external auditory canal. I advised immediate operation. On January 28th, assisted by Dr. J. H. P. Hodgson and E. L. Dow, I opened the mastoid process. Extensive destruction of the bony structures was found, and at least half an ounce of pus filled the cavity. I exposed the sigmoid sinus from the bulb to the knee and opened it, but no clot was present in its lumen, the blood flowing free and clear. The hemorrhage was easily controlled by means of a pledget of iodoform gauze. The dura mater was apparently healthy. Having thoroughly curetted the walls of the cavity I packed the wound firmly with gauze.

January 30th: The wound was dressed and the gauze removed; there was no hemorrhage from the sinus, which looked healthy and was well contracted. Much pus was present.

February 1st: The wound was dressed; the discharge was less.

February 4th: The wound was dressed; it is granulating nicely.

February 8th: The wound was dressed; the patient is steadily improving. From this last date onward, the patient's condition steadily grew better, and by March 9th the wound had entirely healed. The body temperature reached the highest point—101.6° F.—on the third and fourth days following the operation. During convalescence it ranged from 98.2° to 100.4° F.

Case IV.—Elizabeth S——, aged five and one-half years, daughter of a physician, had an attack of the grippe in the early part of February of the present year. An otitis media purulent acuta developed about the 14th of February, and Dr. John Dorning asked me to see the case on the 17th. I found a slight tenderness over the right side of the mastoid, but so slight as to render it doubtful whether it really existed. The discharge from the ear was mucoid in character, and the membrana tympani was only slightly bulging. Adenoids were present. Their removal was advised, but I could not obtain the necessary permission. At this point I would like to suggest for discussion the question whether we should operate for adenoids of the vault of the pharynx during an attack of acute aural inflammation, or should wait until all the acute symptoms had abated. The removal of these growths certainly provides for better drainage of the middle ear through the natural passage, the Eustachian tube, and also gives us the beneficial effect of a considerable local loss of blood. On the other hand, it is undoubtedly true that many cases of acute middle-ear inflammation have arisen from the operation. However, in all cases of acute catarrhal or purulent inflammation of the middle ear, in which I have removed the adenoids (when present) early enough, I have never had occasion to regret taking this step. Of course it is possible that these cases might not have gone on to develop mastoiditis, even if the adenoids had been left *in situ*; but, comparing cases in which the symptoms have been equally severe, I may say that the patients from whom the adenoids have been removed have certainly been discharged cured much earlier than those in whom they were allowed to remain. But to return to the case: I made a thorough paracentesis of the membrana tympani at this time. On February 27th, as the ear was getting worse and the discharge more purulent, I obtained permission to remove the adenoids. At the same time I made another free paracentesis, extending the incision along the upper wall of the canal.

Three days later the discharge was again more marked. The body temperature reached 103.4° F. and the pulse 120, and a slight tenderness was found to exist over the mastoid. An operation was advised. At the father's request, Dr. Fred. Whiting, of this city, was asked to see the case. He agreed with Dr. Dorning and myself as to the advisability of the operation, and kindly consented to present and give us the value of his experience and assistance. The mastoid was thoroughly opened. Although the amount of pus found was small, all the mastoid cells contained appreciable masses of granulation tissue.

On March 4th, the left ear became involved, and a paracentesis of the membrana tympani was done on this side.

On the 8th, the body temperature rose to 102° F., and on the 10th to 105.6° F. Dr. Dorning, for the fourth or fifth time, thoroughly examined the child and found all the other organs of the body normal. The blood was examined for the malarial parasite, but it was not found. It is true, a slight bronchitis existed, but it was so slight that it could not have had any bearing on the temperature.

On the 15th, I again made a paracentesis of the left drum membrane.

On the 18th, the body temperature having risen to 104.8° F., and Dr. Whiting having approved of the proposed step, I opened the mastoid on the left side. The conditions found here were very similar to those found on the right side.

On the 19th the body temperature rose to 99.2° F. at 1 A.M., and to 104° at 1 P.M., falling back to 99.8° at midnight.

On the 20th the temperature record was as follows: 99.2° at 4 A.M.; 105° at 3 P.M.; 102.4° at 8 P.M.

On the 21st, the record was: 102.4° at 8 A.M.; 100.4° at 7 P.M.; 105.4° at 9 P.M.

On the 22d: 105.6° at 1 A.M.; 101° at noon; 106.2° at 5 P.M.; 101° at 11 P.M.

On the 23d; 105° at 1 A.M.; 100° at noon; 106° at midnight.

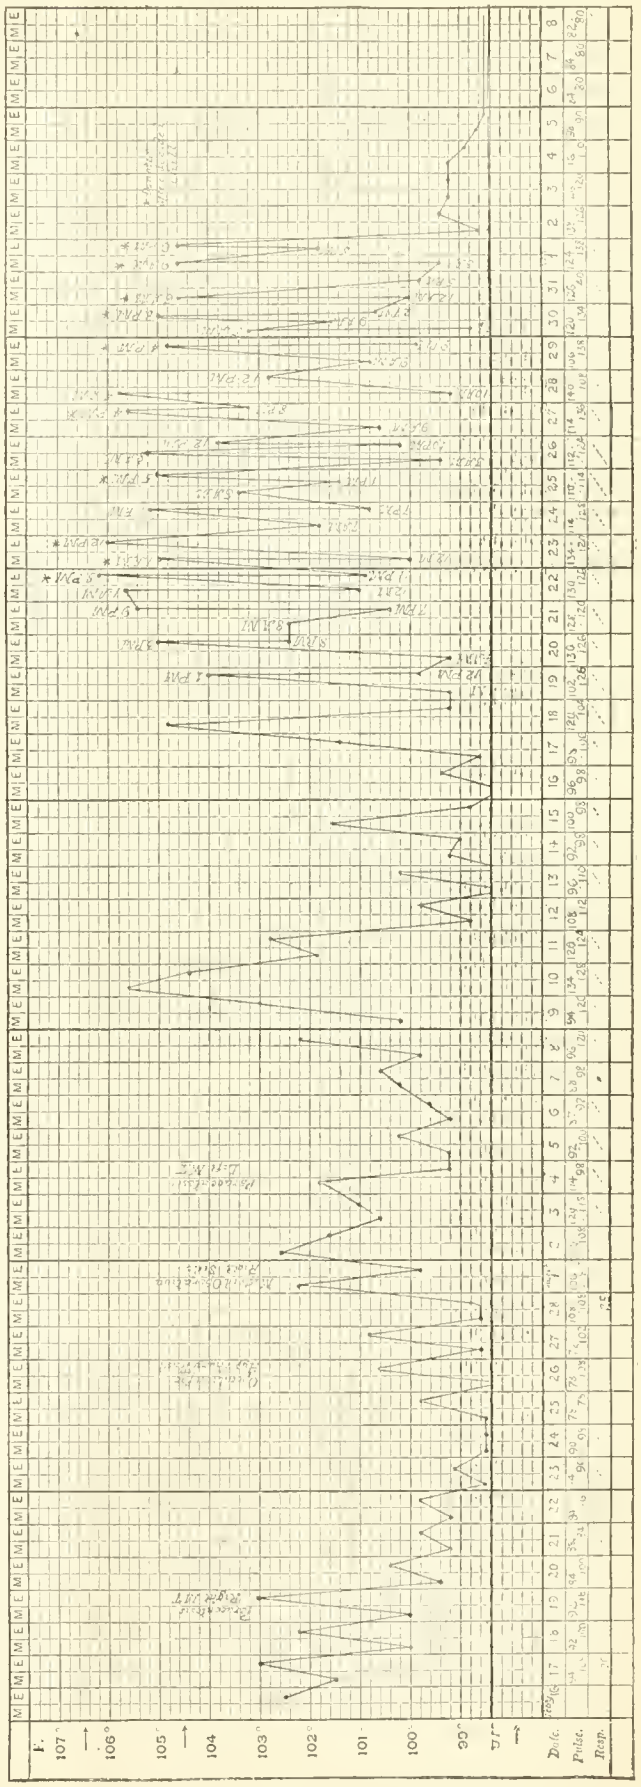
On the 24th: 101.8° at 7 A.M., and so on, as will be seen by the accompanying chart, for fourteen days. (See Chart, Case IV.)

The rise of temperature usually took place after a chill. Absolutely no other symptoms, except a slight tenderness over the right femoral artery, which lasted for four or five days, were at any time perceptible. Drs. Dorning and Whiting joined with me in urging that we be allowed to explore further the mastoid region, to uncover the sigmoid sinus, and if necessary to explore the sinus as also the middle and posterior cranial fossæ. There were absolutely no symptoms besides this fluctuating temperature to warrant this step; but in view of the fact that this was the region which was primarily involved, and in view of the further fact that we could find no other cause for the existing pyæmia, we thought we were justified in the position which we took. But the father, Dr. S——, would not listen to further operative interference.

On the 19th, Dr. Robert F. Weir was asked for his opinion, and he thought that, in view of the lack of other symptoms, we ought to wait a few days for other evidences before exploring. He considered that if, at the end of forty-eight hours, we got no further evidences of disease, and yet the temperature continued to fluctuate, it would then be good surgery to explore. I contended at the time that it was better surgery to explore before we got further symptoms, which latter would mean a further extension of the disease. Dr. Francis L. Delafield was also called in consultation on the 21st, and he advised non-interference until more marked symptoms should appear. I felt at the time that the case was hopeless; but, on the morning of the 2d of April the temperature fell to almost normal and never rose appreciably after that date. The child, after a tedious convalescence, fully recovered.

Though our prognosis was happily proven to be incorrect, and our desire to operate further was proven to be unnecessary, I still feel that the stand we took was the only correct one, and that in a similar case in the future I would not allow the result obtained in the present case to tempt me from further exploring the field of operation. It was suggested by one of the gentlemen that the infection was a wound infection; but as the mastoid was most thoroughly laid open, and as the wound, though sluggish, remained healthy, and with but little suppuration, this did not seem to me to be a likely cause. I had the privilege of seeing one of Dr. Gorham Bacon's cases in which, after a mastoid operation, the body temperature rose to a high point (106° F., I think), while the respiration fell to about ten per minute. In this case Dr. Bacon made an exploration of the sinus and posterior fossæ, and although he found no further lesions, yet after the operation the patient's temperature fluctuated only slightly above the normal, the respirations rapidly rose to about sixteen per minute, and the man proceeded to make an uneventful recovery.

Case V.—On April 5th, Dr. Albert H. Buck was called by Dr. X——, to see a gentleman who was in a comatose condition, and obtained from the former the following history: Acute middle-ear inflammation beginning about six weeks previously, with discharge lasting for one week. On the 4th of April the patient was awakened by severe pain in his head. He called upon his physician, who advised him to go home and apply ice to his head. That evening the patient became unconscious, and he had remained so up to the time of Dr. Buck's visit. During the winter, on two occasions, sugar had been found in the patient's urine. Dr. Buck found no bogginess or redness over the mastoid, but a profuse discharge from the middle ear with stenosis of the canal. He advised an operation as the only means of saving the man's life, and at his request I operated early in the afternoon, the man still being unconscious. With Dr. Franklin Stevens' assistance, I exposed the mastoid cells, and found them infiltrated with pus, but only in small amount. I exposed the sigmoid sinus, and wounded it slightly, causing some hemorrhage. Its walls were very thin. On exploring the tegmen tympani, my probe entered the cranial cavity. I then removed the tegmen tympani, exposing the middle fossæ, and found the dura mater of a dark bluish-red color, bathed in pus, and bulging. I introduced an exploring needle and withdrew about a drachm of pus. I then incised the dura; but although I searched in all directions, I found no further collection of pus. The patient never recovered consciousness; he died a short time after having been placed in bed. I bring this case before the society in the hope that it may call forth a discussion in regard to the question whether we are justified in operating when the patient may be considered to be *in extremis*. The patient certainly, in the case just narrated, had no chance for life without an operation, and while I think his chance with an operation was at best only a very small one, I nevertheless believe we were warranted in taking that small chance. I also cite this case as another one of those unfortunate ones which ought to be a warning to the general practitioner against treating diseases of the ear, acute or chronic, in a slighting manner. There are more patients than we know of, who die primarily from disease of the ear, and which, if seen in time by the aurist, would have their lives prolonged. Dr. Eugene Hodenpyl only recently told me of a case upon which he had performed an autopsy. The man was found unconscious in the street, and the hospital authorities thought it likely that he had been sandbagged. Dr. Hodenpyl,



Case IV.—Elizabeth S——, Aged Five and One-half Years. Mastoiditis (double) complicating the "grippe."

on autopsy, found the man had been a sufferer from purulent otitis media, the discharge having gradually burrowed through the tegmen tympani, and a cerebral abscess having developed, suddenly rupturing, caused the man's death. The statement of Dr. McEwen that "when the tympanic cavity has become the seat of chronic suppuration with ulceration of the mucous membrane into the antrum and mastoid cells, it becomes a standing menace to the safety of the patient. The disease progresses insidiously, and one cannot be certain as to when or where it may end. A person might as well have a charge of dynamite in the mastoid antrum or cells, as one cannot know the moment when accidental circumstances may arise, which may cause infected matter to become widely disseminated all over the cerebro-spinal system. Chronic otorrhœa is much too lightly regarded, and is frequently considered as a mere inconvenience instead of a menace to life"—might only to a less degree be applied to acute cases as well.

It is not so many years ago that I attended the medical school, and yet at that time one of our college professors summed up diseases of the ear in the one word, "wax." There are to-day too many men in the practice of medicine who look upon aural disease as possessing a scarcely larger sphere.

## MAJOR AND MINOR TECHNIQUE OF BASSINI'S OPERATION, AS PERFORMED BY HIMSELF.

By E. WYLLYS ANDREWS, A.M., M.D.,
CHICAGO.

While in northern Italy I made three trips to Padua to see Professor Bassini, who was so kind as to invite me to see some private operations at his house as well as those in his hospital service.

Although doing considerable general and abdominal work, this great Italian surgeon and teacher has an especially large number of hernia operations. His private patients come from distant lands in some cases. Among them I met a Greek gentleman, one from Germany, and a patient from Paris.

An average of more than one radical-cure operation a day is done here, and the wards of the hospital, of course, contain cases in every stage of recovery.

The ancient university at Padua now has thirteen hundred students. It once had an attendance of many thousand, surpassing any university in the world. Among its professors was Galileo. Petrarch, Dante, and Tasso were educated here, as well as Savonarola, Giotto, and many famous men.

Half a mile from the university, near the east wall, is the Spedale Civile, or hospital where the students attend clinics. This hospital is an old and very large building. Professor Bassini speaks of it as not quite modern enough to suit his ideas, but it would be hard to plan one better suited in certain respects to hospital purposes. It surrounds a large court with galleries like cloisters of an abbey, and is spaciously and massively built in three stories. At the entrance gates a room is provided (as is also done in Paris now) where visitors may leave automobiles and bicycles.

The operating-theatre, dressing-rooms, etc., are closely like those in German hospitals. The interesting large wards, four in number, are the largest rooms I ever saw used for this purpose. They extend through two stories—that is, they are at least ten to twelve metres high and have galleries four or five metres above the floor, above which are the only windows. Each ward must be fifty or sixty metres long and one-third as wide, as there are rows of twenty-four beds on each side without crowding, and a double row was placed down the centre for half the length. The male surgical ward contained seventy-six occupied beds and space for ninety-six in all. The adjoining ward of the same dimensions was separated only by a low screen, so that the two rooms were in reality one immense chamber of an L shape, which, but for this separating screen, would have formed one ward of over one hundred and fifty beds.

The great size of these rooms, like some public hall or cathedral, took away all sense of crowding, and I can see no real objections to the plan unless it might be difficulties in administration and nursing.

The hour for operating is 6 A.M. In order to see all the minor preparations one must be present at 5 A.M.

Those who care to read what follows will find a rather minute account of the little steps in the work as I saw it, the general features of the Bassini radical-cure method being assumed to be known to the reader. I have received so many visits and inquiries from physicians who were looking up radical-cure work at home that I am sure a very general movement in the direction of treating hernia surgically must be on foot in America.

Whatever may be the value of either of the American methods, it must be remembered that they follow the Bassini rather than the Kocher or Macewen type. Bassini must be given the credit of having started us all on the right path, hence too careful a study of his own technique cannot be made.

I have seen the Bassini operation done by many operators in Europe and America, sometimes poorly and sometimes very skilfully, but nowhere is it done in all details as it is here in Padua. Perhaps it may interest some to know just how Bassini himself puts in each suture, ties his knots, holds his knife, etc.

Personally, I believe that success in radical-cure operations is a result of smooth and rapid work. So much seems to depend upon getting the parts united with a minimum of handling and stretching that an unvarying routine in the technique is quite essential. Only by uniformity can the operator train himself and assistants to know each step in advance, and to avoid all tentative and experimental efforts and all false moves.

The technique in the operations of Bassini, and his assistant Dr. Stiasni, who sometimes takes his place, is unvarying in the precision of its smallest detail. With either operator the work moves from start to finish with a smoothness almost rhythmical.

Dr. Gaetano Facchetti, another assistant, gives anæsthetics when Bassini operates, but acts as first assistant to Stiasni when he operates. Both these gentlemen are with Professor Bassini in his private work also. All can speak German in a measured, scholarly way. Some of Professor Bassini's best papers have been in that language.

The time required by Bassini for an inguinal herniotomy is twenty or twenty-five minutes, for a double rupture thirty-five or forty-five minutes. In Gussenbauer's and other Vienna clinics I have observed the time to be about double this on the average for the Bassini operation, although a fairly large goitre was removed in eighteen minutes.

No difference in any detail could be noticed in different operations by Bassini, whether in the clinic or his private practice. The same early hour is set for all cases, at least in summer. One description applies, therefore, to all the operations I saw.

The patient is shaved and cleansed on the previous day, but not dressed with sublimate gauze or indeed any covering. About 5 A.M. the assistants start the sterilizers in which the various rubber aprons and table covers, as well as the sheets, towels, etc., are placed. The hands of the operators receive an exceed-

ingly prolonged scrubbing—nearly thirty minutes—before being placed in sublimate solution, which is strong—3 : 1,000.

The patient is prepared before anæsthesia by (1) prolonged scrubbing with soap and water; (2) copious washing with decinormal saline solution; (3) 3 : 1,000 sublimate solution copiously applied on compresses and poured over the parts. Rubber cloth leg covers like boots are now drawn up over the legs and thighs. Thick red rubber cloths are placed over the upper part of the body. Gauze pieces one metre square are laid over the intervening parts in several layers, and more sublimate 3 : 1,000 is poured over them. The usual tying of gauze over the penis is attended to. Sublimate solution is used rather frequently before the incision and after the wound is closed, but none is poured into the cut tissues, although the hands and sponges are washed in bowls of it.

During the last part of the preparation the patient is rapidly put under chloroform, his knees having been secured by straps to the table.

The gauze over the inguinal region is now cut open from the pubes to the iliac spine, uncovering a space a little larger than the skin incision. The latter is made by drawing the skin and fat into a fold transverse to Poupart's ligament. This is seized by the operator's left thumb and forefinger, while the assistant grasps the same fold about an inch away. About 7 to 10 cm. is the height of the fold drawn up, and this is quickly incised between the operator's and assistant's hands, making an incision 12 to 18 cm. long and 3 or 4 cm. above Poupart's ligament. This method is rapid, the aponeurosis of the external oblique being laid bare at a single stroke and the pillars of the ring exposed. Half a dozen bleeding points are at once seized. The superficial epigastric vessels are divided near the middle of the incision. The canal is laid open, not by dividing the ring and external oblique on a director, but merely with a stroke or two of the scalpel from above downward parallel to the coarse tendinous fibres of the aponeurosis. The dissection of the external oblique is quickly made with the handle of the scalpel until Poupart's ligament is exposed on its inner aspect. The cord mass, containing the cremaster, hernial sac, and spermatic cord, is now raised by a blunt dissection and any lobules of loose fat stripped away as high up as possible. The cremaster muscle, when developed into large strings, is removed in the same way, often between ligatures.

The isolating of the sac is usually begun at its neck. After being stripped from the cord, it is often seen that the testis has been drawn up into the wound, but this is not objectionable. Even in congenital hernia the isolation of the sac is usually accomplished at least at its cervical portion. The neck of the sac is now detached from the internal ring by loosening the parietal peritoneum for 2 cm. all around it. The deep epigastric vessels will always be seen if this has gone far enough. It is now certain that the sac can be removed at a point high enough to insure that no funnel or even dimple will be left leading down into the repaired ring. Contrast this with the Kocher method in which such a tubular process must always remain, inasmuch as the stump of the sac is left in the internal ring. The sac is now opened widely at its fundus, and its whole interior inspected. If no adherent contents are found a clamp is at once placed upon its neck as high as possible. Adherent masses of omentum are returned after careful hæmostasis, and such masses are removed only when they have become much thickened and hardened as in certain old hernias.

The method of removing the sac is by tying around its neck above the clamp a strong silk ligature. In small sacs this is sufficient; in large ones the ends of the same ligature are threaded upon a needle passed through the stump and tied around over the first loop. The sac is now cut off just outside the clamp and the latter removed. The elastic peritoneum draws the stump well inside the abdomen, and, of course, the subsequent work is purely extraperitoneal.

Now the dissection of the peritoneum away from the internal ring, which has already been mentioned, has also had the effect of loosening the transversalis fascia and internal oblique muscle so that the margins of the internal ring are free and even undermined. These, as every one knows, are the structures to be included in the Bassini operation in the first or deep line of suture, intended to restore the enlarged ring to its normal size. To facilitate the insertion of these stitches a forceps is made to grasp the transversalis and internal oblique, pointing from the internal ring inward, one blade being just outside the peritoneum, *i.e.*, the blades grasp the whole of the posterior wall except the peritoneum. This gives a ready means of handling and raising the structures in placing the deep stitches. A flat director is also used in some cases at this stage, thrust into the internal ring to push the posterior wall forward, and to steady it as the needle enters its substance. I attach some value to this little step in the technique, since it is obviously difficult without it to know the exact depth to which the needle enters the muscle, and whether it gets any of the transversalis fascia, unless one goes deep enough to risk puncturing the peritoneal cavity.

The insertion of this deep suture line is the essential and important feature of the operation. The divided external oblique aponeurosis is held apart by retractors, so that the inner aspect of Poupart's ligament is accessible and visible. The cord is held outside the canal by a loop of silk clamped with an artery forceps to the gauze covering the abdomen. Good-sized silk previously sterilized by boiling in glycerin is taken from the antiseptic and threaded by the operator's own hands upon a semicircular self-threading needle. This is done at the moment of using. A needle holder is used for the two deep suture lines, but for the skin suture the needle is held in the fingers.

The deep stitches are placed beginning very close to the pubic bone. The first one or two may, in some cases, include part of the rectus muscle and sheath. Each stitch enters the transversalis and internal oblique 1.5 cm. from their lower margin, and makes exit at that margin. The needle then penetrates the shelving edge of Poupart's ligament from within outward. From four to six such stitches are placed behind the cord, the last one narrowing the internal ring until it fits tightly around the cord and forceps blade. The order of tying these stitches is the opposite of their insertion. The upper one, that nearest the cord, is first adjusted and the others follow in succession downward. The distance between these stitches is considerable—1.5 or 2 cm. Their effect is not only to restore the length and obliquity of the canal, but to invert the upper or muscular segment like a Lembert suture, and to draw it somewhat behind the ligament and not merely against it. In other words, we have a sort of overlapping or imbrication here, giving broad surfaces of union.

The cord being replaced in the repaired canal, the second suture, that reuniting the external oblique aponeurosis, is placed as follows: The outer angle is lifted on a blunt hook and two silk stitches are placed here and tied. A running or continuous suture is then rapidly inserted until the pillars of the external ring are reached. Here one or two separate stitches are now placed to bring it to the proper size. This form of suture is rapid and gives abundant tension at the two ends without danger of puckering or shortening the incision. All the arteries are now tied with silk.

The final step of closing the skin is by a continuous silk suture, inserted with a half-curved needle held with the fingers only.

The pinched-up flaps are both transfixed by the needle about 1 cm. from their cut edges. While the needle is sticking through the skin, the slack of the thread is wound twice around its point, after which it is pushed through. This forms a continuous buttonhole suture. Each part is easily given the proper tension, as there is no back slip. When completed, it is somewhat ridge-shaped, the deeper parts being well coapted. Professor Bassini also uses this suture after cœliotomy and in operations in general, with good results.

Drainage is seldom employed in these herniotomies, but in occasional cases in which there is obstinate oozing a rubber tube is inserted at a point some distance from the suture line.

The first and practically the only dressing is by moist sublimate compresses of gauze. Over this are large masses of salicylic cotton made to envelop the hips, thighs, and abdomen, front and back. The patient is then drawn down upon two steel rods projecting from the end of the table, and the whole enveloped in wet starch and lime bandages from the middle of the thighs to the middle of the abdomen. This forms a firm support when dry, but is not so rigid as plaster of Paris The steel rods are included in the bandage and are drawn out when the patient is laid upon the car or bed. A similar dressing is used by Bassini after many operations—nephrectomy, hip and shoulder resection, and amputation of the breast.

The post-operative history of these herniotomies is of great interest. The time of the first and only redressing is about the eighth day. I had opportunity to study the history charts and see the dressings removed in a large number, and saw without exception the same result, viz., definitive primary healing with a level temperature below 99° F. after the first forty-eight hours. Not a drop of secretion or sign of infection was present in any case.

When the skin suture is removed on the eighth day, a light gauze dressing is placed over the wound. The patient is at once allowed to leave his bed and go home, with advice to remove this dressing in a few days himself. No truss or support is ever used, and no limit to exercise is enjoined.

Recurrences are very rare, less than five per cent. in all probability, after two or three years have elapsed. Of course no relapses occur immediately. There is practically no danger to life from this operation. As I have often insisted, the question of recurrence is bound up with that of stitch abscesses. I do not know with what success such accidents are avoided here, and there are no exact statistics accessible, but in a large series I saw not one instance of infection.

In talking over this side of the subject with Professor Bassini, he stated the case very concisely by remarking: "Naturally, as this is a plastic operation, primary union is essential to success. Sepsis prevents this union as in all plastic work." To this may be added another and earlier saying of Bassini, made when he first began his operative work on hernia: "*L'ernia è una malattia meccanica.*"

---

**Phlegmonous Infiltration.**—In cases of phlegmonous infiltration I favor, above all other measures, the application of an ointment composed of resorcin, 5 parts; ichthyol, 10 parts; mercurial ointment, 35 parts; lanolin, 50 parts. Under the influence of this antiseptic and sorbefacient preparation and of moist heat, one may see many phlegmonous infiltrations assume a kindlier type, and may even perhaps secure the actual absorption of pus.—Roswell Park.

## Progress of Medical Science.

**Tuberculosis.** — In concluding an essay entitled "The Struggle against Tuberculosis," Dr. Edward O. Otis says, in the *Boston Medical and Surgical Journal* of September 21st:

"Let me outline a plan for a systematic scheme of prevention in a city like this.

"1. Knowledge of all cases of tuberculosis and their habitat, and the power to control and supervise them; this knowledge to be obtained either by including consumption among the infectious and communicable diseases and requiring notification as with them—which I believe is the only thorough way—or by urging physicians through circulars from the board of health, frequently repeated, to report all cases coming within their observation, especially among the poor, or wherever there is doubt as to the proper disposal of the sputum.

"2. Instruction of the public as to the dangers of tuberculosis and their avoidance by circulars similar to those issued by the Pennsylvania Society for the Prevention of Tuberculosis. This is already done, I believe, to a greater or less extent.

"3. Compulsory disinfection or renovation of premises occupied by a consumptive, or in which a consumptive has died, before they can again be let or occupied.

"4. Hospital accommodations in especial buildings for poor consumptives and those of limited means, situated in or near the city, and receiving free all stages of the disease alike. Two such institutions, with a capacity of one hundred and fifty beds each, or three with one hundred beds each, would probably afford accommodation for nine hundred cases annually on the basis of an average residence of four months.

"5. One or more sanatoria proper in the country for the open-air treatment, not more than two or three hours distant from the city, where the incipient cases and those likely to be benefited by such treatment can be transferred from the city institutions. Rutland already accomplishes this to a limited extent.

"6. Free examination of sputum for tubercle bacilli, as is already done by the city and State.

"7. Regulations against spitting in public halls, conveyances and upon the sidewalks, such as already are in force in our street-car system, and, in addition, the placing of spittoons in halls, waiting-rooms, stores, workshops, out-patient waiting-rooms, and possibly street-cars. In the writer's opinion, spitting properly conducted is a cleanly habit, and the deposit of sputum in appropriate receptacles is to be encouraged rather than in handkerchiefs or in the stomach. It seems a hardship to prohibit promiscuous spitting without making provision for a safe performance of this act, necessary to many persons.

"8. The establishment of especial out-patient clinics so that the consumptive cases can be segregated, and receive more detailed attention and instruction for themselves and friends as to how they may avoid communicating the disease.

"9 Control of the city milk supply, by requiring all dealers to furnish satisfactory evidence that the cows from which their milk is obtained have been found free from tuberculosis by the tuberculin test, which test is to be repeated at stated intervals.

"10. Inspection of animals slaughtered for food, and of all meat sent into the city. Possibly compulsory disinfection of old clothes in pawnshops, as advocated by Professor Roche, of Dublin.

"Of all these, especial isolating hospitals are, in the writer's opinion, most urgent and most important."

It will be remembered that at the late international

congress much stress was laid upon several of these points, notably the establishment of sanatoria and open-air treatment.

**Intussusception.**—In a paper contributing two cases to the list of operations in the adult Dr. John C. Munro (*Boston Medical and Surgical Journal*, September 14th) adds fourteen instances of reduction or resection which have been reported since the last tables were compiled, making seventy-two cases altogether.

Of twenty-one recoveries after reduction—including the cases of Perceval (1888), Stretton (1894), and Barker (1897)—thirteen were in the ileocæcal or colic region, four were iliac, one jejunal, and three unknown Thirteen were chronic cases seven acute, and one unknown.

Of thirteen fatal reductions—including the cases of Davies-Colley, White (1889), Richardson (1892)—nine were ileocolic, one each was iliac and jejunal, and two were unknown. Seven were acute and six were chronic, probably some of the latter being operated upon during an acute exacerbation. Shock and peritonitis were the main causes of fatal issue.

Of seventeen recoveries after resection—including the cases of Hartley (1892), Wassiljew and Munro (1898)—fourteen were ileocolic and one each was iliac, colic, and jejunal. Six were acute or chronic with acute exacerbations, and nine were chronic, while two were unknown. In two cases (Mikulicz and Wassiljew) the resection was secondary to an artificial anus.

Of twenty-one fatal resections—including the cases of Abbe (1891), Senn, Robson, and Monro (1897)—nine were ileocolic, seven iliac, one colic, two jejunal, and two unknown. Fourteen were acute or chronic with acute exacerbations, five were chronic, and two unknown. One (Esmarch) was secondary to artificial anus. Nearly all the patients died of peritonitis or shock.

The jejunum was involved in only five of these cases, including the one now reported: (1) In White's case, an acute invagination ten inches long and two and one-half feet from the pylorus, the patient died on the table, the operation being abandoned. (2) In Stutsgaard's case, caused by a lipoma and of unknown duration, the patient died in five days of peritonitis after resection of 128 cm. (3) Robson's case, of seven days' duration, ended fatally after resection of four feet and an end-to-end anastomosis. (4) Borch's case of acute ileojejunal invagination resulted in recovery after disinvagination.

The first of the author's patients died, the second recovered after resection of thirty-two inches of jejunum.

**Increase of Weight in Artificially Fed Infants.**—Koplik (*Jahrbuch für Kinderheilkunde*, September) after an experience of nine years at the laboratory of the Good Samaritan Dispensary, with artificially fed healthy and sick infants, presents a method of modifying and preserving milk which has given very good results. For purposes of study, infants under nine months of age were carefully observed for as long a time as is possible in such an institution, each infant having a special card upon which its weight was noted at stated intervals. He divides his cases, all of which were under nine months of age, into (A) infants who from birth or soon after were fed on modified cow's milk, (B) infants who were fed with the breast and cow's milk.

(A) All milk was sterilized at 90–92° C. and then rapidly cooled. The modified milk in both classes of cases was the same and was composed of equal parts of cow's milk and distilled water, with the addition of six per cent. recrystallized sugar of milk, *i.e.*, the so-called Heubner-Hofmann's mixture. Infants under three months of age were given three ounces, older infants one ounce more for each month of life until eight ounces were taken, when pure milk was substituted. The number of daily feedings varied from seven to eight. In newly born infants under one month, the mothers were advised to give one and a half ounces. All infants were weighed systematically. This Heubner-Hofmann mixture contains water 90.57, proteids 1.78, fat 1.85, sugar 5.44, ash 0.36, and is practically the same as that recommended by Soxhlet. From the foregoing it is seen that the mixture is poor in fat and well diluted. Lime-water was not added. It was deemed advisable to procure a mixture in which the solution of albuminoids and casein was such as to assure their easy assimilation, and the aforementioned mixture answered the purpose. Under all circumstances, the loss in feeding with cow's milk is far greater than in feeding with mother's milk. Again, the increase of weight in an infant fed on cow's milk, with or without additional substances, is very irregular, and this becomes all the greater when the quantity and quality of the food vary Cammerer first showed that infants who were nourished according to the methods of ten to twenty years ago were not, as a rule, so well nourished as those who have been fed according to the more recent methods of preparation, modification, and sterilization. Koplik then gives tables of his own and of Cammerer, showing the daily increase of weight, and points out how closely they correspond. Thus at the twelfth to sixteenth week Koplik has a daily increase of 23.6 gm. and Cammerer 22 gm.; at the twenty-eighth to thirty-second week Koplik has 15.6 gm. and Cammerer 16 gm. Comparing his results with those of Cammerer, Koplik says that they are very encouraging and lead us to the conclusion that the results of infant feeding, when relatively large numbers are concerned, and when the same methods of general dilution and preparation are used, are practically the same in all countries. The difference in the daily increase is relatively very small, although it must be admitted that in individual instances the difference in certain infants may be greater than in others. In other words, with constant care and avoidance of everything which tends to make the infant ill or reduce its weight, some infants will gain in weight, but not necessarily in such a distinct ratio as breast-fed infants. Some infants increase in weight with great strides, others more gradually. Allowance must be given in these cases for poor hygienic surroundings and lack of parental care, which results in diarrhœa or other diseases which necessitate the discontinuance of the milk diet or its diminution. In private practice the results have been far better, in the author's experience. In those cases in which the babies were fed on the breast and bottle, the results have been remarkably good, even though the baby received a full breast-feeding once, twice, or three times in twenty-four hours in addition to the bottle. The number of bottle-feedings to be given in these cases daily was calculated from the quantity of milk which could be furnished by the deficient breasts. If the breasts furnished two feedings, the remaining six feedings for the twenty-four hours were given from the bottle. The number of bottles was diminished if the breast was capable of more feedings. Briefly stated, the daily increase and the weight of such infants at the end of nine months ran quite closely to those shown by Cammerer for exclusively breast-fed infants. The author then takes up the modern methods of modifying milk for infant feeding, and after discussing the methods of Meigs, Rotch, and Gaertner, thinks that even with exact percentages obtainable through such elaborate methods as that of Rotch, we do not solve the problem of infant feeding in every case. In other words, there is something essentially foreign in cow's milk to the

infant's assimilation. In such cases—and they are not a few—infants fail to thrive on any of the known methods.

**Survival for Three Weeks from the Passage of a Crow-Bar through the Vertical Diameter of the Abdominal Cavity.**—Miller (*Edinburgh Medical Journal*, September, 1899) reports the case of a strong Irishman, twenty years old, who, while standing on a ledge, in the process of dressing a railway embankment by means of a long pointed crow-bar, fell upon the implement, the point of which entered his right thigh in front and emerged below the right shoulder posteriorly. A companion who witnessed the occurrence hastened to the patient's assistance, and with some difficulty succeeded in the withdrawal of the crow-bar. The patient was then conveyed to the hospital, partly by locomotive engine and partly by carriage, for a distance of eighteen miles. On admission he was found to be much collapsed, with weak and rapid pulse, cyanosed face, and cold extremities. Stimulants were administered in hot milk, hot bottles were applied, and morphine was injected subcutaneously. The patient soon recovered sufficiently to permit of a detailed examination. The point of the crow-bar had entered about four inches below the line of junction of the thigh with the pubis. Its course was through the subcutaneous tissues of the limb, beneath Poupart's ligament, and through the abdominal cavity. The wound of exit was situated about one and a half inches below the angle of the right scapula. There was not much bleeding from the wound of entrance. The femur was uninjured, and the patient could flex and extend the thigh without difficulty. The femoral artery could be detected pulsating feebly to the outside of a swelling beneath Poupart's ligament. This swelling gurgled distinctly on pressure. The tenth and eleventh ribs were fractured and comminuted, and a splinter from the tenth had been thrust upward so as to penetrate the pleural cavity. There was considerable oozing from the thoracic wound. The surrounding tissues were emphysematous, and air passed freely in and out of the aperture. The wound was valvular, the opening in the skin being at a higher level than the injured ribs; but on drawing the skin and the subcutaneous tissue downward the fractured bone could be easily seen by electric-lamp light. The splinter that caused the pleural wound was caught with forceps and removed. For an hour or two after admission there was considerable disturbance of respiration, and aeration of the blood seemed to be effected with difficulty. The pulse was extremely weak and irregular, and the face was deeply cyanosed. By and by, however, respiration and circulation became quiet and regular. The patient slept at intervals, and in the evening stated that he felt no discomfort whatever. The temperature was 102.2° F. Eighteen ounces of clear healthy urine were drawn off, and morphine, gr. ¼, was administered hypodermically every four hours. Toward morning on the following day vomiting set in, and seemed to give relief. The vomited matter consisted of bile-stained fluid, tinged also slightly with blood, and it smelled sour. The temperature fell to 99° F., the pulse to 100. Flatus passed freely. The wounds appeared healthy, and after being thoroughly irrigated with 1 : 40 carbolic-acid solution were stuffed with iodoform gauze. For several days the patient remained in much the same condition, vomiting being almost incessant, relieved occasionally by ice and sometimes by the application of a sinapism to the epigastrium. Morphine was given less frequently. The urine for the most part was passed voluntarily and in small amount. Rectal enemas failed to relieve the constipation. Tympanitic distention of the abdomen set in. In the course of a week the patient's condition became critical. The nights were restless and disturbed by vomiting. The temperature was subnormal, and the extremities were cold. The pulse was small, slow, and compressible. The thoracic wound, however, was healthy, and the wound in the thigh dry and gangrenous. The bowels were now moved for the first time, and the abdominal distention became less and the vomiting not so constant. Improvement followed also in the general condition. The facies became less anxious, the pulse quieter and more regular and full, while the temperature stood at normal. Later the bowels became loose, and the pulse small, rapid, irregular, and feeble. The patient's features became more and more anxious, emaciation progressed, and the abdominal distention increased. The thoracic wound discharged a large quantity of pus, and daily irrigation with carbolic-acid solution was practised. A drainage-tube was inserted. The femoral wound became healthy and tended to granulate. After the lapse of another week the patient began to expectorate a peculiar slaty-greenish sputum tinged at times with blood. He complained of pain in the right side in the region of the wound, and relief followed each dressing, when large quantities of pus were gotten rid of. The face, nose, eyebrows, and forehead became covered with a thick herpetic eruption. The patient grew progressively worse, with exhausting diarrhœa, and death took place twenty-one days after the accident. At the autopsy, a wound was found on the right side, four inches below the pubic spine, measuring one and one-half inches vertically and two and a half inches transversely. A second wound was present in the right infrascapular region in a line with the angle of the scapula, occupying partly the sixth, seventh, and eighth interspaces, and measuring two inches vertically and one and one-quarter inches transversely. On opening the abdomen the peritoneum was found thickened and adherent to the abdominal wall. The coils of intestine were distended and matted together. The omentum was represented by a thin membranous layer, with only traces of fat on its surface. A line of redness marked the upper line of adhesion between the coils of intestine. In the right iliac region, bowel, peritoneum, and abdominal wall were closely adherent. The cæcum at its upper extremity was deeply injected. In the process of separating adhesions between the bowel and the liver a tear, of the size of a threepenny piece, was made into the upper wall of the duodenum, and from this issued a large quantity of intensely yellow, thin fluid. The liver was enlarged. On its lower aspect, in the middle line and near the outer border, was a torn, ragged surface, about two and a half inches in its longest diameter, *i.e.*, transversely to the organ. A lacerated wound, somewhat similar in size and appearance to the former, was found on the upper and external aspect of the organ. There was a wound in the thoracic wall below the insertion of the diaphragm, situated about two and one-half inches external to the vertebral column, two inches in its vertical and one inch in its transverse extent. The tenth and eleventh ribs were fractured and comminuted in this situation. The right pleural cavity was occupied by a large amount of sero-purulent fluid.

**The Concentration of the Urine and of the Blood in Relation to Disease of the Kidneys and to Uræmia.**—As the result of a careful and elaborate clinical study, reported in the *Deutsches Archiv für klinische Medicin*, Nos. 1 and 2, vol. 65, Lindemann formulates the following conclusions: The degree of concentration of the urine may be determined with great accuracy from a study of the freezing-point. This mode of determination is to be preferred to others, such as the specific gravity and the amount of dry residue, as it is not based upon the weight of the constituent sub-

stances, but upon the number of their molecules. The determination of the concentration of the urine from this point of view permits a conclusion as to the functional capability of the kidneys. The determination of the reduction in the freezing-point of the urine, together with a knowledge of the daily amount, permits of a differentiation of albuminuria unassociated with inflammatory processes in the kidneys from that dependent upon nephritis. While the freezing-point of normal urine passed in average amount varies between $-1.3^\circ$ and $-2.3^\circ$ C., and variations above or below these figures, as for instance $-0.9^\circ$ and $-2.7^\circ$ C., have been observed only exceptionally, the reduction in the freezing-point, and thus also the concentration, of the urine, is much less in the presence of inflammation of the kidneys. With average amounts of urine the freezing-point is usually below $-1^\circ$ C. The reduction in freezing-point exhibits characteristic differences between parenchymatous and interstitial nephritis. The diminution in concentration is much more considerable in the former than in the latter, and is especially conspicuous when the amount of urine is small. It is not rarely so marked that the urine has a lower freezing-point than normal blood serum. The determination of the concentration of the urine will not aid in the differentiation of acute and chronic parenchymatous nephritis from one another. On the other hand, it will permit of the recognition of the restoration to health that takes place with recovery, the reduction in the freezing-point then increasing and returning to normal. The reduction in the freezing-point frequently permits a recognition of the transition of chronic parenchymatous nephritis to secondary contraction. It again increases and attains proportions similar to those observed with primary genuine contracting kidney. Other forms of albuminuria, *e.g.*, those attending stasis, fever, cystitis, and pyelitis, are characterized by an absence of any lessening in the reduction of the freezing-point. An exception is constituted by conditions of collapse, in which small amounts of urine are associated with marked reduction in concentration. If in a case of cystitis or pyelitis reduction in the concentration of the urine with average amounts takes place, an extension of the inflammatory process from the pelvis of the kidney to the renal structure itself becomes probable. The estimation of the total amount of substances eliminated through the urine in the presence of renal inflammation frequently permits a conclusion as to the retention of urinary substances. In cases of nephritis the concentration of the blood serum remains normal so long as uræmic symptoms do not appear. When uræmia sets in, the concentration of the blood, and with it the osmotic pressure thereof, is increased. The reduction in the freezing-point may be as high as $-0.7^\circ$ C. This increase in osmotic pressure is the constitutional expression of the existing disturbance associated with uræmia. Most of the conditions found in uræmia are most satisfactorily explained upon the basis of this increase in osmotic pressure. The manifestations which appear after injection of large amounts of concentrated saline solutions into the blood are the same as those that attend uræmia. They occur with the increased concentration of the blood if the elimination of the accumulated substances from the blood can no longer take place because the receptive capability of the tissues and the organs of the body is exhausted.

**A New Blood Stain.**—Jenner recommends in *The Lancet*, No. 3,937, 1899, a blood stain that he contends is easily made, that keeps well, that fixes and stains ordinary blood films in two minutes, and that demonstrates with perfect clearness and in well-marked contrasts red blood discs, blood platelets, the nuclei of white blood cells, the fine granules of polymorphonuclear leucocytes, coarse oxyphile granules, basophile granules, and when present erythroblasts, bacteria, malarial parasites, and filariæ. Equal parts of from a 1.2-per-cent. to a 1.25-per-cent. solution of Grübler's water-soluble eosin, of yellow shade, in distilled water, and of a one-per-cent. solution of Grübler's medicinal methylene blue, also in distilled water, are mixed together in an open basin and thoroughly stirred with a glass rod. The mixture may with advantage be left for twenty-four hours. It is next filtered, and the residue is dried either in the air or more quickly in an incubator or water oven. When quite dry the residue is scraped off the filter paper and is powdered. It is then shaken up with distilled water and washed on a filter, when the washings should be of a thin, dirty purplish color. Finally it is again dried and powdered, and may be stored in suitable bottles. For use, 0.5 gm. of the powder is thoroughly shaken up with pure methyl alcohol such as is used for analytical purposes. The solution keeps well. Cover-glass preparations are made in the ordinary way, and upon them, as soon as the films (which should be extremely thin) are dry, a few drops of the staining and fixing solution are poured, no previous fixation being required. The cover glass must have been absolutely clean and free from every trace of acid or alkali. After they have been cleaned and well washed in distilled water they should be kept in absolute alcohol only. The specimen is covered with a watch-glass to prevent evaporation and consequent precipitation. In from one to three minutes the stain is rapidly poured off, and the specimen is at once rinsed in distilled water till the film has a pink color, which usually occurs in from five to ten seconds. It is then dried either very high up over a flame, or (better) by agitation in the air, and is mounted in xylol balsam. The red blood cells appear of a terra-cotta color; the nuclei of the white corpuscles are blue; the platelets are mauve; the granules of the polymorphonuclear white cells and of myelocytes are red; the granules of the basophile (mast) cells when present are dark violet; and bacteria, malarial parasites, or filariæ are blue. The stain may be equally well made by dissolving the eosin and the medicinal methylene blue directly in absolute methylic alcohol and mixing them in the proportion given, viz., 125 c.c. of a 0.5 per-cent. solution of the eosin and 100 c.c. of a 0.5 per-cent. solution of medicinal methylene blue.

**Dermatomyositis.**—Oppenheim (*Berliner klinische Wochenschrift*, September 11, 1899) reports a case of that rare condition originally described by Wagner, Hepp, and Unverricht as polymyositis, and in a modified form described by Unverricht as dermatomyositis. The patient was a boy, eight years old, who for nine months had complained of pain in the back and in the extremities, that at first attracted little attention, but subsequently increased in severity and gave rise to increasing difficulty of movement. In the course of a little while, changes appeared in the skin and the soft parts, namely, redness of the face, especially in the neighborhood of the eyelids and the cheeks, and of the hand; also swelling in the same parts, as well as in the thighs and in the inguinal and adductor regions. The patient complained, further, of burning and pain in the mouth and pharynx, especially on swallowing. In addition, it was ascertained that on several occasions the temperature had been elevated considerably, and that the patient had suffered from profuse sweats. In an etiological connection it was learned only that the patient had lived in a damp basement; he had besides suffered a slight traumatism. The patient assumed a constrained and rigid posture, with want of mobility dependent upon pain in movement, and exhibited in attempts at elevation of the arm,

or movement of the head, but above all by any movements of the trunk or those involving the vertebræ and their muscles. In addition, some muscles exhibited paresis and atrophy; others a condition of abnormal tension. The paresis and atrophy were most marked in the deltoid, as well as in the flexors of the forearm, and were associated with diminution in electrical irritability. The tension and the shortening were also conspicuous in the biceps, which on attempt at extension became a rigid, almost inelastic band. Like conditions were present also in the muscles of the back and the thigh. In the muscles of the shoulder and the arm, especially in the deltoid, the biceps, the brachialis internus, and still more in the muscles of the thighs, especially the upper portion of the adductors, instead of the sensation yielded normally by muscular tissue there was conveyed the impression of a dense, rigid tendinous structure. The muscles, further, were extremely sensitive to pressure, and tenderness was manifest also on active movement and on electrical stimulation. The face presented an erythematous or pseudo-erysipelatous redness, most marked about the eyelids. The upper lids presented a tumid, slightly œdematous appearance, and at the angles of the eye there existed a moderate degree of inflammation. Redness and swelling were evident also upon the dorsum of the hand, and over the metacarpo-phalangeal and interphalangeal joints were rounded pale, atrophic areas, resembling cicatrices, which succeeded upon previous œdema. Similar spots were present also upon other parts of the trunk and arm. The skin of the auricles was bluish-red, slightly desquamated, and so thin that the veins were distinctly visible. The mucous membrane of the cheeks, of the hard and soft palate, and of the tongue was deeply reddened. The redness of the mucous membrane of the cheeks was diffuse, that of the hard palate more punctate, while the appearance of the tongue was suggestive of raw meat. The gums were purplish red. The cervical and epitrochlear glands were enlarged and painful. There was no derangement of common sensibility or of the special senses. The tendon reflexes were normal or slightly increased. The function of the sphincters was preserved. The general condition was influenced only by the pain. No abnormity of the viscera was detected. Histologically the lesion is found to consist in a cellular infiltration of the muscular tissue, in part diffuse, in part circumscribed. The internal perimysium is thickened in places, and the primitive fibres are in part atrophied.

**Amenorrhœa Associated with Raynaud's Disease and Pulmonary Tuberculosis.**—Byers describes, in *The Lancet* of August 26th, a group of cases presenting in conjunction (1) diminished or arrested menstruation, (2) local, symmetrical asphyxia of the extremities and especially the hands, and (3) pulmonary tuberculosis; and he reports four illustrative instances. The presence of any single one of these symptoms is quite common, but it is probable that the association is comparatively rare. All of the symptoms did not appear contemporaneously in the cases reported. In all, the local asphyxia and the irregularity of menstruation were marked when the patients first came under observation. In two, the pulmonary tuberculosis was also coexistent with the other features mentioned, while in two other patients it developed at a subsequent period.

**Headache and Eye Affections.**—In a paper by Dr. S. D. Risley (*Journal of the American Medical Association*, September 23d) on the relations of headache to affections of the eye, the writer believes the following conclusions may be regarded as established by clinical experience: (1) Abnormalities of the ocular apparatus are in a large group of patients the sole and sufficient cause of headache. (2) These abnormalities of vision may be the unsuspected cause, and therefore the absence of symptoms obviously referable to the eyes does not exclude them as an etiological factor in headache, insomnia, vertigo, petit chorea in children, and certain stomach derangements. (3) The recent or sudden development of symptoms, after attacks of severe illness, as typhoid fever, the exanthemata, etc., or in association with more or less acute exacerbations of some general dyscrasia, is not sufficient evidence against ocular participation in causing the symptoms. (4) The participation of the eyes as an etiological factor in headache can be positively excluded only in the absence of ocular disease or after the most painstaking correction of any existing error of refraction or abnormality of binocular balance. (5) For the relief of reflex symptoms accurate corrections are essential, and these can be secured only by the more or less prolonged use of a strong cycloplegic. (6) Immediate relief by these corrections in a large group of patients is not to be expected, since the pain is frequently due to associated pathological conditions of the fundus oculi, and these require time for cure.

**Epilepsy and Its Treatment.**—In a contribution to the study of epilepsy and its treatment Wisłocki (*Gazeta Lekarska*, No. 19, 1899) advocates the milk diet. Complete disappearance of attacks was noted in some instances and decrease in number in others so treated. It has the advantage over the bromides of not disagreeing, so that its employment may be continued indefinitely. When not well borne it can be alternated with courses of the bromides. The improvement under the exclusive milk diet leads the observer to believe that attacks are due to irregularities in nutritive exchanges in individuals whose cerebral cortex is in a state of superexcitability.

**Diabetes Mellitus Complicated by Peripheral Neuritis and Retinal Changes.**—Hawthorne has reported, in *The Lancet* of September 30, 1899, the case of a woman, sixty-seven years old, who had complained of failing sight for twelve months, of double vision which came on suddenly, and of pain in the right eye which had been present for three weeks. Examination disclosed absolute paralysis of outward movement of the right eye. Each lens showed numerous peripheral striæ (ordinary senile cataract). In the fundus of the left eye were two considerable patches, consisting of yellowish-white, more or less confluent lustrous spots. Each patch was somewhat triangular or fan-shaped, the apex being at the macula. There were also a number of isolated spots of a similar character scattered irregularly over the posterior part of the fundus. The fundus of the right eye appeared to be normal. There was no central scotoma in either visual field. The urine was pale, of a specific gravity of 1.038, and it contained a large amount of sugar, but no albumin. The knee jerks could not be elicited. The patient had enjoyed fairly good health except that within the last two years she had had two severe attacks of sciatica (each in the left limb), and six months previously she had been confined to bed for some weeks with weakness of the heart. Her husband had died from angina pectoris twelve months before. She had had nine children, of whom four had died from pulmonary tuberculosis. There was no history of gout or rheumatism in the family. On inquiry the woman admitted that the daily amount of urine had been excessive for some six or seven years, and that during this time she had also suffered from thirst. She had been told four years previously that she had diabetes. After the lapse of some thirteen months the paresis of the external rectus had disappeared, while the changes in the left fundus had become much more advanced.

# MEDICAL RECORD:

## RELATIVE VALUE OF PROFESSIONAL SERVICES.

THE question of relative professional incomes is one which always appeals to the physician who can take any comfort in comparing his lot with that of other brain workers. It is some consolation to know that he is not alone in the matter of receiving inadequate pay for services rendered. His brethren of the cloth appear from all accounts to be worse off than he is in that respect, as witness their complaints which have been aired recently in numerous newspaper articles. It is the misery which likes company which gives to these discussions a widespread and telling interest.

While the doctor's income is always an unknown quantity oftentimes to himself by reason of doubtful bills, but still oftener to impertinent inquirers, the clergyman's salary is known and read by all members of his congregation, and is a fixed figure if the promises of his trustees are faithfully kept. Thus we have from one point of view at least a fixed standard of comparison with what the doctor alone knows to be his own share of profits from his work.

The naked fact of inadequate sums received by the doctor is his own skeleton in the closet, but he can covertly and privately match it with the published accounts of salaries with which the ministers must be satisfied. Altogether it must be admitted that the medical man, inadequate as his earnings may be, is much more fortunate than the clergyman. The latter, it is true, gets his rent free, with occasional yearly donations of potatoes, hay, flour, and the like, but his living expenses must be within the limits of an income scarcely equal to that of an average mechanic with regular daily employment.

It is somewhat of a surprise to learn that a first-class clergyman in a country town averages only from five hundred to eight hundred dollars as yearly salary, while those in the large cities are not enough above those figures to make up the relative differences in incidental expenses of living. The latter amounts are said to range from one thousand to twelve hundred dollars yearly. Certainly the average doctor must do much better than this, otherwise he must either run in debt or look for some other occupation. If the doctor in practice must make any living at all, he is bound to calculate on a sum one-third more and perhaps double that which the preacher can get. We are now speaking of the average man in both professions, it being well known that special skill and recognized ability in either calling always command proportionately increased remuneration.

In some respects the physician and the clergyman are equally handicapped by conditions which make their clients more or less independent of their special services. The doctor has the free dispensaries, the beneficiary lodges, and the greedy clinics, while the minister sees his flock spurring away on the Sunday bicycle, sneaking for the train with the golf bag, or reading the Sunday papers for the latest gospel heresies. Still there is one advantage for the doctor over the clergyman: men, women, and children will get sick and must have treatment, in spite of quackery, clinics, and faith cures, while the would-be Christian is too ready to postpone repentance until it is too late to do church, minister, or himself any good either from a spiritual or pecuniary standpoint.

With both professions there is a sentiment of so-called charity and a sympathy for suffering spiritual, mental, or physical that hinders the more direct appeals for ready compensation which appertain to most callings. This attribute certainly does not cut a figure with the lawyer, whose retainer before and after the trial is a matter entirely in his own hands as the controller of the funds in his direct keeping. In his case the client gets what is left before all is gone, while ofttimes the physician and preacher must wait until their legitimate share has been divided and exhausted among the numerous and importunate creditors who work their claims on what is conventionally termed purely business principles. Thus it is that the doctor particularly is the best friend in need and the last to be considered when his indispensable services have been conscientiously and dutifully rendered. In these practical days it is no longer an optional and generous honorarium to be freely given, but a prosaic bill that is too frequently entirely ignored, or worse, is cowardly disputed.

## MEDICAL EXPERT TESTIMONY.

THE discussion before the New York State Medical Association on expert medical testimony brought out many important questions for consideration. The expression of opinion as to the advisability of changing present methods being based mainly on the strictly legal point of view, there was an opportunity for reconciling many conflicting interests existing between the two professions concerned in the case. The great importance of getting at the real facts in the case of a jury trial and impartially interpreting them is the main issue at stake. Everything must depend upon the unbiassed opinion of an expert in any given case. How the latter can be fairly obtained when the experts are paid by their respective sides has always been a matter of doubt with the jury. The general results of such a system have been open contradiction of testimony from opposite sides, and a nec-

essary confusion in the minds of the twelve men who must weigh all the pros and cons. Thus it has come about that the expert is looked upon with as much distrust as the ordinary witness with whom he may be associated.

Very many radical measures of reform have been suggested, which are reasonably taking in theory but very difficult of practical application. Some of these were referred to by Judge Bartlett in his able review of the subject before the meeting in question. Concerning the advisability of the appointment of an independent expert commission to whom all strictly scientific questions should be submitted, he has much to say. As this is one of the pet measures suggested by the medical profession, it is extremely interesting to learn his views on the subject. While, theoretically speaking, he believes that such a commission appointed by the judge would be an ideal one and would satisfy a jury, he nevertheless is in grave doubt as to its constitutionality, inasmuch as it would debar litigants from obtaining experts of their own selection. The main argument against such a procedure is the fact that all human judgment is liable to err, and that the widest latitude should be given against all chances of mistake, whether they be in a commission or in a single individual. Especially should this condition be guaranteed by the elimination of all show of arbitrary power on the part of the official witnesses. His objections on such grounds are certainly reasonable and just. They are further strengthened by the conceivability that incompetent persons may be appointed with correspondingly deplorable results.

He says very pertinently in this connection: "In what position would a physician accused of malpractice and condemned by an incompetent board find himself if he were not permitted to call on his brother physicians to defend his position and show wherein the findings of the official report were at fault?" Certainly the same difficulty in obtaining justice would apply to any case in which any contrary view as to the justice of any absolute opinion would be reasonably tenable.

The situation can be modified to a great degree by cross-examination of the experts. Nothing short of this should be thought of as a reasonable protection against what would otherwise be an arbitrary and absurd assumption of human infallibility. Again it is claimed by the learned judge, with good reason, that no expert who is employed to advise counsel regarding the scientific conduct of a case should be allowed to give testimony. Obviously such a witness must be biassed in spite of his best intentions to the contrary. The influence of large fees for expert opinion is also a governing factor in the same direction, although it is comforting to believe that they do not prevent even hired witnesses from being ordinarily honest. The only safeguard for all parties concerned is a guaranteed fee for telling the simple truth from a strictly scientific standpoint, irrespective of the side represented.

It is to be regretted that the distinguished jurist, after his study of the subject, has no other practical procedure to advocate than the permissive appointment by the judge of an expert who shall be agreeable to both parties in the litigation, and with the understanding that no others are to be called. This, it would seem, is compressing the issues within a comparatively small compass of individual judgment. The only seeming advantage of such a measure over that of a mixed commission would be the absence of constant contradictions on cross-examination. Altogether, after looking into the general question in all its varied phases, it would seem desirable, if such a thing could be done, to secure an enactment for the permissive appointment by the judge of a mixed commission of experts which should be under pay of the State, and which should decide on all abstract questions of scientific fact, should be subject to cross-examination by both litigating parties, and should be debarred from acting in any advisory capacity to either counsel.

## EX-SURGEON-GENERAL TRYON'S RETIREMENT.

On September 24th the active list of the navy lost one of its most popular and efficient officers, under the law compelling retirement on reaching the age of sixty-two years, however fully in the possession of all his faculties such an officer may be.

Medical Director J. Rufus Tryon, who has thus been placed on the retired list, with the full rank of rear-admiral, leaves a record in the service of having as surgeon-general brought the medical corps and the naval hospitals to that high state of excellence which was commended throughout the world during the war with Spain, and which resulted in such an astonishingly insignificant loss of life afloat, from wounds or disease, during and after the period of hostilities. To the thorough system he built up, and to the professional attainments of the surgeons which he demanded, as well as to the modern sanitary practice and refinements which he insisted upon in the design of the new American war-ships, has been attributed the abnormally low sick and death rate in the navy which has excited unbounded admiration at home and abroad.

The recommendations persisted in during his term of office, for the establishment of a naval hospital corps and permanent ambulance ships to accompany our fleets, were speedily adopted at the outbreak of the war, and have reflected merited praise upon the medical department of the navy. The naval hospitals throughout the country, the Naval Laboratory and Department of Instruction at New York, and the Museum of Hygiene at Washington, perfected in their arrangements during his administration, are all model institutions.

Rear-Admiral Tryon is a native New Yorker, and will make Manhattan his residence in retirement. He entered the service as assistant surgeon in 1863, and was assigned to the West Gulf blockading squadron under Admiral Farragut, where he remained for two years' arduous duty. After the fight at Mobile Bay he had the wounded under his skilful care at the Pensacola Naval Hospital. The following two years Dr. Tryon was attached to the Boston Naval Hospital, then

crowded with the sick and wounded from the South, and at this time, by special orders from the department, he made a report upon the treatment of the wounded at that place during the conflict. In consequence of the ability he showed in this report he was brougth to Washington, and, in spite of his junior rank, was made assistant to the surgeon-general as well as promoted to the grade of passed assistant surgeon. He remained in this position four years, and then joined the Asiatic station, where he was promoted to the rank of surgeon in 1873.

During the frightful epidemic of 1871 he established and had charge of the temporary hospital at Yokohama, and was afterward selected to design and build the existing hospital there, which remains to this day a model institution and which was until last year the sole foreign possession of the United States.

From this work he returned to New York on special duty, only to be hurried to Pensacola to take care of naval patients during the yellow-fever epidemic there in the summer of 1873. He went as United States delegate to the International Medical Congress at Copenhagen, Denmark, in 1884. In 1891, Union College, where he graduated in the class of 1858, recognized his accomplishments with the honorary degree of Ph.D., and in 1895 conferred upon him the degree of LL.D. He was promoted to medical inspector in 1891, and the next two years was fleet surgeon on the flag-ship *Chicago*, of the White Squadron, under Admiral Walker. During this cruise he received the decoration of the Busto del Libertador for services rendered the wounded of both parties at Macuto, during the Venezuelan revolution, and afterward was awarded a bronze medal by the Red Cross Society of Venezuela. On his return to the United States he was promoted to be surgeon-general, with the rank of commodore and chief of the Bureau of Medicine and Surgery, on May 10, 1893.

Upon retiring from this position at the expiration of his four years' term he went to Spain as United States representative to the International Congress of Hygiene, where he had the distinction of being the last official American to have an audience with the Queen, war at that moment being a foregone conclusion. During the recent war Dr. Tryon has been continuously on duty as general inspector of naval hospitals. In his retirement after his long and useful service he has the best wishes of his many professional friends.

---

**Moving Against Consumptives in Colorado.**—Active measures are being taken by the Charity Organization Society of Denver to lessen the practice of sending indigent consumptives to Colorado. It is charged that physicians in the East advise the removal of patients having no reasonable expectation of benefit from the climate of Colorado, or who have no means to support themselves while getting something to do. These people without money soon become a burden to the charitable societies, and must be supported or returned to their homes at public expense.

## News of the Week.

**Thirteenth International Congress of Medicine at Paris, August 2 to 9, 1900.**—The American committee of the Thirteenth International Medical Congress met at the University Club, Philadelphia, October 21st, at 3 P.M., at the call of Dr. William Osler. There were present: Dr. W. W. Keen, president of the American Medical Association (in the chair); Dr. George M. Sternberg, surgeon-general of the United States army; Dr. William K. Van Reypen, surgeon-general of the United States navy; Dr. Walter Wyman, surgeon-general of the United States Marine-Hospital service; Dr. Horace G. Miller, president of the American Otological Society; Dr. E. D. Fisher, president of the American Neurological Association; Dr. George J. Engelmann, president of the American Gynæcological Society; Dr. H. W. Stelwagon, president of the American Dermatological Association; Dr. Samuel Johnston, president of the American Laryngological Association; Dr. R. F. Weir, president of the American Surgical Association; Dr. A. Jacobi, president of the American Climatological Association; Dr. E. G. Janeway, president of the Association of American Physicians; Dr. Henry Koplik, president of the American Pediatric Society.

Letters of regret at inability to attend the meeting were reported from Dr. O. F. Wadsworth, president of the American Ophthalmological Society; Dr. James Bell, president of the American Association of Genito-Urinary Surgeons; Dr. H. M. Sherman, president of the American Orthopedic Association; Dr. R. H. Chittenden, president of the American Physiological Society; Dr. B. G. Wilder, president of the Association of American Anatomists; Dr. H. P. Bowditch, president of the Congress of American Physicians and Surgeons (absent in Europe); Dr. B. Holly Smith, president of the American Dental Association.

Dr. Osler stated that in May he had received instructions from the secretary of the Congress in Paris to organize the American National Committee. After consultation with Dr. W. W. Keen, the president of the American Medical Association, and Dr. H. P. Bowditch, the president of the Congress of American Physicians and Surgeons, he had nominated as members of the committee the presidents of the American Medical Association, of the Congress of American Physicians and Surgeons, and of the constituent societies composing the same, the surgeons-general of the army, of the navy, and of the Marine-Hospital service, and, at Dr. Keen's suggestion, the president of the American Dental Association.

Dr. Sternberg moved, seconded by Dr. R. F. Weir, that the American Committee of the Thirteenth International Medical Congress consist of the gentlemen just named. The motion was carried.

Dr. Osler then read the following letter of instructions, which he had received from Dr. Chauffard, the general secretary:

"HONORED COLLEAGUES: I have the honor to state that I have sent you (1) A package of subscription

blanks ('forms of adhesion'); (2) some account books with stubs.

"1. Subscription Blanks ('Forms of Adhesion'). Please distribute these blanks as widely as possible, sending them to universities, hospitals, learned societies—in a word, wherever you deem it possible to obtain subscribers to the Congress. We have thought it wise to prepare these blanks in such form that they may be of a uniform type for all countries, which will facilitate the task of classification of the members. Please insist that your fellow-countrymen conform to all the directions which are therein contained. Pray distribute, together with our subscription blanks, announcements of your own, indicating the name and address of the representative of your committee to whom the subscribers in your country should address the subscription blanks when filled, as well as the corresponding funds. These subscription blanks should be collated by you, and sent to us in groups of fifty, with the visiting-cards and the corresponding stubs of the record book (*vide infra*). It is then understood that these blanks constitute simply a sort of propaganda, and that we shall consider as members of the Congress only those gentlemen who shall have sent to your committee the amount of their subscription, and shall have received in exchange the receipt from your account book (leaflet C).

"2. Account Books. The three account books which we have sent you (series 171 to series 173) represent each fifty subscriptions to the Congress. We would call your attention especially to the detailed directions which appear on the first page of the book. The stubs of this book (leaflets A and B), which serve us at the same time for registration of the members and for our financial accounts, we beg you to fill out as legibly as possible, and not to forget to place the stamp of your committee at the point indicated on each of the three leaflets. This stamp will eventually indicate to us the origin of each subscription. This is but the first instalment, and we shall be glad to send you, if it be necessary, new account books as soon as you may request them. We beg you to send us the stubs as soon as each of the account books is filled, together with the amount of the corresponding subscriptions and the filled subscription blanks. We trust that these account books will facilitate the laborious task in which you have kindly lent us your assistance. Pray understand that we are entirely at your service to furnish you any further explanations which you may desire concerning our registration of members. Yours, etc.,

"A. Chauffard,
"*Secretary-General.*"

It will thus be seen that the work of each national committee of this Congress is very different from that heretofore intrusted to them. Physicians in this country who wish to become members of the Congress must apply to the secretary of the national committee, who will forward a blank of application, which is to be filled in and returned to the secretary, with a fee of $5.

Dr. Janeway moved, seconded by Dr. Wyman, that Dr. Osler be empowered to appoint a physician as secretary to the committee, and to secure such aid as would be required to carry on the work. The question of meeting the expenses of the committee was left to the chairman. If each national committee is expected to meet its own expenses, it was agreed either to call upon the treasurer of the societies represented in the committee, or upon the individual members.

It was moved by Dr. Engelmann, seconded by Dr. Stelwagon, that the medical journals of the country be requested to aid in making known as widely as possible the conditions under which registration in the Congress may be effected.

While it is to be understood that the central committee wishes the subscriptions to be sent to the secretary of the national committee, Rule 3 of the Congress provides that persons wishing to be members may forward their subscriptions to the treasurer-general of the Congress.

Dr. Osler announced that he would nominate Dr. Henry Barton Jacobs, 3 West Franklin Street, Baltimore, Md., as secretary of the committee, to whom all applications for blanks should be sent.

**Hog Cholera** has broken out in a virulent form in the vicinity of Doe Run, near West Chester, Pa., and a large number of animals have died.

**Dr. Thomas G. Ashton** has been elected clinical professor of medicine in the Woman's Medical College of Pennsylvania.

**A New Sanatorium for Consumptives in Italy.**—The Countess of Ravaschieri has, according to the Italian journals, given all her extensive possessions in Pozzuoli to the Italian Hygienic Society, with the provision that a sanatorium for consumptives is to be erected there and maintained by the income from the estates.

**Typhoid Fever in Williamsburg.**—A meeting of property owners and residents of a section of Williamsburg was held last Friday to urge upon the board of health the adoption of measures looking to the sanitary improvement of their district. The immediate cause of the meeting was the unusual prevalence of typhoid fever in the neighborhood. Resolutions were passed protesting against the inadequate sewer system and the filthy condition of the streets in that part of Brooklyn Borough.

**The Army Medical Department at Manila.**—Recent despatches sent to the newspapers from Hong Kong having stated that the medical service at Manila was inefficient, the surgeon-general has made a report of the actual condition there to the Secretary of War. This report states that there are sixty-one regular army surgeons in Manila and seventy-seven contract surgeons, in addition to the medical officers with each regiment, and when all the troops now under orders have arrived, there will be a total of two hundred and fifty-one medical officers to care for sixty thousand men. There are now in the Philippines one hundred and seventy-five surgeons for thirty-one thousand three hundred and thirty-four enlisted men. These medical officers are assisted by nine hundred and eighty-nine hospital stewards and nurses and seventy women

nurses. Of hospital tents there are twelve hundred and thirty-two on the spot, and two hundred and forty are on the way to Manila. Each of these tents will accommodate six men, so that eighty-eight hundred and thirty-two sick soldiers can be cared for at one time. In addition to the tents there are accommodation for two thousand in the permanent hospitals at Manila. As the largest number of sick reported by the medical officers in charge has been eighteen hundred and forty-seven, it is evident that there are accommodations in the hospitals and hospital tents for more than five times as many sick as have been reported. The army with General Otis has double the number of medical officers usually supplied to an army of its size, besides a full regiment of hospital stewards and nurses, most of whom have had medical training. The hospital ships *Relief* and *Missouri* are on the way to the Philippines now, and on their arrival there will be beds for six hundred more sick.

**The Plague** continues its advance upon Europe, having now probably invaded Spain. A dispatch from Toledo, dated October 20th, states that a serious outbreak of a disease suspected to be the bubonic plague has occurred in the village of Quero, near Toledo. No fewer than two hundred and thirty persons have been attacked. The alarm recently caused in Samara by the appearance there of a fatal and unusual form of disease appears to have subsided. The town was visited by the Prince of Oldenburg and two other members of the plague commission, who recently published the result of their inquiries. The cases were limited to eight, four of which proved fatal. A careful inquiry was made, and the disease was found to have been a severe form of malaria, accompanied by croupous pneumonia and erysipelas, and having nothing in common with bubonic or pneumonic plague. The precautionary measures have therefore been abandoned, and Samara is declared plague-free. A disease said to be the plague has appeared at Santos, Brazil. The disease appeared in a house inhabited by Italians. During the ten days ending October 21st, there were nine cases, three of which had resulted fatally. Quarantine has been declared against Santos by Argentina and Uruguay and also by the other Brazilian ports.

**A New Book by Weir Mitchell.**—Among the books announced for early publication is "The Autobiography of a Quack," by Dr. Weir Mitchell. The title is somewhat ambiguous if not misleading.

**A New Hospital in Richmond.**—A new public hospital in Richmond, Va., will be called the Charlotte Williams Hospital, in memory of a daughter of John L. Williams. Mr. Williams has contributed $100,000 toward its endowment.

**Foreign Practitioners in Japan.**—We learn from the *Sei-I-Kwai Medical Journal* that since the new medical-practice law has come into force in Japan about sixty foreigners have applied for a license. Licenses have been granted to fifteen physicians and four dentists, and charters have been granted to seven dispensaries.

**Philadelphia Hospital.**—Dr. G. E. Pfahler has been elected assistant chief resident physician in succession to Dr. S. F. Gilpin resigned. Opposition has been offered to, and action has been deferred upon, the following resolution submitted at a recent meeting of the Department of Charities and Correction: "That the attending pathologist of the Philadelphia Hospital be allowed the privilege of utilizing the pathological specimens at that institution to make autopsies for the purposes of instruction."

**Malaria and Mosquitoes.**—An interesting letter from Dr. Donald Ross, who is investigating the relations between the malaria parasite and the mosquito at Sierra Leone, is published in *The Times*, London. He says: "We have now practically finished our work here. We have found: (*a*) That local species of anopheles carry malaria; (*b*) that these species breed in a few stagnant puddles. The practical results to be derived from the facts which we have obtained will depend solely on the government and medical profession here. . . . Of course, we could kill most of the anopheles grubs here in a few hours with kerosene oil, and the thing will be done shortly. But this won't be enough. It is necessary that the operations be continued systematically, and that some of the more dangerous puddles be drained. . . . For many scientific reasons we have come to the conclusion that the truly malarial fever is caused here solely by the mosquito —probably entirely by the anopheles species. We estimate, then, that most of the malarial fever here can be got rid of at almost no cost except of a little energy on the part of the local authorities."—*The Hospital.*

**Mutual Aid Association of the Philadelphia County Medical Society.**—The annual report of the Mutual Aid Association of the Philadelphia County Medical Society for the year ending June 3, 1899, shows that during the year a number of new members and one benefactor were added to the roll. The actual assets increased $1,211.80. The total assets equal $12,905.55.

**The Dutch Red Cross Society** has decided to send to the Transvaal, by way of Lorenzo Marquez, an ambulance service capable of caring for twenty-five patients. Dr. Lingebeck, ex-president of the Red Cross Society in the Transvaal, will have charge of the service. He will take with him three other physicians and seven women and four men nurses.

**Dysentery in Japan.**—A dispatch to the New York *Times* states that a terrible epidemic of dysentery is sweeping over Japan, with fatal results. Official statistics show that out of 50,000 persons attacked nearly 12,000 have died this year up to September 14th. Authorities state that 100,000 cases will be recorded by the end of October. Dysentery was unknown in Japan until 1880, when it was brought by ship from abroad. That year it killed 1,300 people. Thereafter it spread steadily until 1893, when 41,000 persons perished. Out of 1,000,000 cases recorded from 1880 to the end of 1898, 247,000 proved fatal. According to the *Sei-I-Kwai Medical Journal*, Kitasato

and Shiga have been experimenting with a curative serum treatment which has so far been fairly successful. At the end of August some sixty patients with dysentery had been treated in Kitasato's hospital, and of them only one had died. The experimenters claim that a cure may be obtained in almost every case, no matter what its seeming gravity, provided only that the treatment is begun early enough.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 21, 1899. October 14th.—Surgeon O. D. Norton detached from the *Badger* when put out of commission, and ordered to temporary duty on the *Ranger;* on arrival at the Asiatic station ordered to the *Monadnock.* Passed Assistant Surgeon L. L. Young ordered to be examined at the Mare Island navy yard, October 24th, thence home and to wait orders. Passed Assistant Surgeon J. Stoughton detached from the *Monadnock* when relieved, and ordered to the *Bennington.* Assistant Surgeon J. J. Snyder ordered to the *New Orleans,* October 18th. Assistant Surgeon D. G. Beebe detached from the *Bennington,* when relieved, and ordered to the *Ranger.* October 16th.—Passed Assistant Surgeon J. C. Rosenbleuth detached from treatment at the naval hospital, Chelsea, Mass., and granted sick leave for one month. Assistant Surgeon R. W. Plummer detached from the hospital, New York navy yard, and ordered to temporary duty on the *New Orleans* for passage to the Asiatic station. October 17th.—Passed Assistant Surgeon H. D. Wilson directed to proceed home and to wait orders. October 18th.—Passed Assistant Surgeon H. D. Wilson, order of October 17th modified; detached from duty on the *Solace.* October 19th.—Surgeon H. T. Percy detached from the *Olympia* when put out of commission, and ordered home and to wait orders. Assistant Surgeon D. H. Carpenter detached from the *Olympia* when put out of commission, and ordered home and to wait orders. Pharmacist A. Hammar detached from the *Olympia* when put out of commission, and ordered to the Mare Island navy yard. Assistant Surgeon E. Thompson detached from the *Manila* and ordered to the *Celtic.* Assistant Surgeon W. E. High detached from the *Celtic* and ordered to the *Manila.* Assistant Surgeon H. H. Haas detached from treatment at naval hospital, Yokohama, Japan, and ordered to the *Baltimore.*

**Philadelphia Hospital.**—Councils' committee on charities and corrections has recommended the appropriation of $60,000 for enlarging buildings in the insane department of the Philadelphia Hospital; and also an increase in the salary of the chief resident physician from $2,500 to $2,750.

**Yellow Fever** is gradually decreasing in Key West, but has now appeared at Miami, Fla. Several suspicious cases having been reported from Miami, the State health officer made an investigation, with the result that yellow fever has been officially declared to exist in that city. Five cases, at the time the report was made, had been seen and a positive diagnosis made, and it was believed that there were several others in the city. The infection is widely distributed, but is mild in character. In order to arrest the progress of the epidemic the depopulation of the town is recommended. Havana and Santiago were not depopulated, yet the fever was subdued there. Some of the health officers in Florida and elsewhere might take a trip to Cuba to learn the value of sanitation in the prevention of epidemics. A report from Santiago, dated October 18th, announces that the city is entirely free from yellow fever. At Vera Cruz the fever is decreasing in consequence of improved sanitary conditions and cooler weather. One yellow-fever patient who had received treatment with Sanarelli's serum has died at Cordoba. Several new cases have appeared at Orizaba, and a number of deaths from the disease have occurred there.

**Centigrade and Fahrenheit.**—Dr. W. J. Swift writes: A simple and more easily remembered formula for the conversion of Centigrade degrees into Fahrenheit degrees and *vice versa*, than that given by Dr. Whiton in the MEDICAL RECORD of October 14th, is the following: $\frac{9}{5}$ C. + 32 = F. $\frac{5}{9}$ (F. − 32) = C.

**An Operation on the Czar.**—It is reported that the Czar's skull was trephined at Darmstadt on October 14th, in the hope of relieving certain cerebral symptoms from which he has been suffering. His trouble dates from as assault which was made upon him several years ago when travelling in Japan. It is asserted that the operation was successful, though it is not yet possible to say what the ultimate benefit will be.

**The Superintendency of the Utica State Hospital.**—As the result of the civil-service examination held for the appointment of a superintendent for the State Hospital at Utica, the following-named candidates have been declared eligible, ranking in the order named; Harold L. Palmer, State Hospital, Utica; Henry P. Frost, State Hospital, Buffalo; William L. Russell, State Hospital, Willard; Jelvin Courtney, Hudson State Hospital, Poughkeepsie.

**Obituary Notes.**—DR. HENRY JUDSON KELLY died of pneumonia at his home in this city, on October 15th, aged forty-two years. Dr. Kelly was born in this city in 1857, and was graduated from the College of Physicians and Surgeons in 1880. He later served a term on the house staff of the New York Hospital. A widow and four children survive him.—DR. CHIPP was found dead in his office at White Lake, N. Y., on October 20th. Death was due to an overdose of morphine. He was twenty-six years of age.—DR. WALTER S. KIMBALL, one of the oldest homœopathic physicians in New Jersey, died at Lakewood on October 21st. He was born in Lewis County, N. Y., in 1828, and was graduated from the New York Homœopathic Medical College in 1863. He was for a year president of the Homœopathic State Medical Society of New Jersey. He leaves a widow and six children.—DR. PHILIP SCHEU died at his home in this city, on October 21st, after a week's illness. He was born in New York in 1858, and was graduated from the College of Physicians and Surgeons in 1884.

# Society Reports.

## NEW YORK STATE MEDICAL ASSOCIATION.

*Sixteenth Annual Meeting, Held in the New York Academy of Medicine, October 24, 25, and 26, 1899.*

JOSEPH D. BRYANT, M.D., OF NEW YORK, PRESIDENT.

*First Day—Tuesday, October 24th.*

THE meeting was called to order by the president, Dr. Joseph D. Bryant, of New York, promptly at ten o'clock, in the large hall of the Academy of Medicine.

**Report of the Committee of Arrangements.**—This report was presented by the chairman of the committee, DR. FREDERICK HOLME WIGGIN.

**Address by the President—The Influence of the Medical Practitioner on Medical Practice.**—DR. JOSEPH D. BRYANT delivered the annual address, which was on the above topic. After touching briefly upon some of the salient points in the history of medical education, the author dwelt at length upon that mode of life which seemed best fitted to allow the medical practitioner to do the most good to his fellow-men. The position taken is perhaps best summed up in these closing words of the speaker: "Knowledge is a hill that few may hope to climb; duty is the path that all may hope to tread."

**Report of the Council.**—This report showed that the library of the association contained at present nine thousand seven hundred and sixty-eight volumes, in addition to many pamphlets. The financial status of the association was most flourishing.

**Report of the Committee on Charities.**—This was presented by the chairman, DR. WICKES WASHBURN. The history of the events leading up to the enactment of the dispensary bill was fully considered, and an account given of the later steps taken in conjunction with the State board of charities and others well known to be identified with the work of organized charity. The committee had also taken an active interest in the question of how the squandering of public money by private hospitals and similar institutions could best be checked. Regarding the proposed establishment of State sanatoria for consumptives, the committee took the ground that, unless the farm-colony system could be included in the plan, it was better to suspend action for the present.

**Report of the Committee on Legislation.**—DR. E. ELIOT HARRIS, the chairman, presented in a few words an outline of the work that had been accomplished. He stated that the committee had carefully followed the course of one hundred and ninety bills before the legislature, and had felt compelled, in the interests not only of the profession, but of the public at large, to take active steps to kill most of these bills. He had been assured that the death of many of these pernicious measures had been brought about through the untiring efforts of this committee.

**Alcohol as a General Stimulant and Heart Tonic; Its Use to the Animal Economy in Health and Disease.**—DR. THOMAS J. HILLIS, of New York, read a paper with this title. He took the ground that for every one who fell a victim to the immoderate use of alcohol hundreds were benefited. Alcohol should no more be an object of indiscriminate condemnation because it slew its thousands, than should electricity because it too was responsible for the sacrifice of many lives. Each, in its proper place, was a benefit to humanity. The failure of alcohol in the sick-room was often to be attributed to using it at the wrong time, in improper doses, and irregularly. The chief factor in determining whether or not alcohol should be used was the state of the stomach. Alcohol was often demanded in the later stages of pneumonia, when there was extensive lung involvement, and when there had been a prolonged high temperature. In a given case, alcohol might be a poison to-day and a physiological necessity to-morrow. Alcohol should never be given in lingering diseases, or in convalescence from acute ones if the stomach was irritable. Alcohol should never be taken immediately after eating; it could not aid digestion, and by its bulk and its action in coagulating albuminoids it must interfere with the proper action of the digestive organs. When used before eating, it sometimes served as an aid to the digestive process through the stimulation of the gastric glands. Alcohol was most beneficial when taken about three hours after a meal. The author's conclusions were, that alcohol was "the sheet-anchor of the intelligent and conscientious physician" when the heart was handicapped by disease, and "the drug *par excellence* in the whole field of therapeutics," best able to tide over a crisis in certain pulmonary and other conditions common to the human subject.

DR. FRANK D. REESE, of Cortland, characterized the paper as utterly lacking in new information, and thoroughly unscientific.

DR. H. D. DIDAMA, of Syracuse, said that although he was not anxious to lay himself open to the charge of not being an intelligent and conscientious physician, he would declare most positively that, in his hands at least, alcohol was not a sheet-anchor in the treatment of any disease. Personally, he did not prescribe it at all for his patients, or take it as a beverage to combat fatigue, and it seemed to him but right that the evidence of those physicians who, like himself, had abandoned the use of alcohol in therapeutics should carry with it more weight than the statements of those physicians who prescribed it almost constantly. But this was not all. For example, Nansen had not found it necessary or even expedient to give his men a drop of alcohol while in the Arctic regions. This subject of the effect of alcohol was attracting much true scientific study at the present day, and attention had been once more called to the fact that alcohol did not really strengthen the pulse, but, on the contrary, quickened and weakened it.

DR. H. O. MARCY, of Boston, recalled his experience in the army years ago, to the effect that alcoholics did not combat fatigue. He said that the author of the paper had neglected to mention the important fact that, through the agency of the stomach juice, alcohol was decomposed into an ether. This would explain certain puzzling but well-authenticated facts learned from experience.

DR. HILLIS, in closing, stoutly maintained that there were no true heart tonics in the whole materia medica except nux vomica and alcohol.

**The Necessity for Exact Evidence in Treating Scientific Subjects.**—DR. WICKES WASHBURN, of New York, read this paper. His contention was that facts were more commonly reported than were correct conclusions drawn therefrom, and instanced some of the hasty generalizations that had been made, and accepted without question, by a large part of the profession. Among these were the errors that had arisen from observations on the presence of certain pathogenic bacilli in given cases. The discrepancies that had arisen in this connection were largely explicable on the theory of differences in soil. The presence or absence of bacilli of any kind should not be accepted, without concurrent facts, as indicating a given disease; but simply as confirming the clinical symptoms when present, or serving as a warning when found in healthy persons.

**The Physician as a Factor in Education.**—DR. FRANK OVERTON, of Suffolk County, read this paper,

which was a plea for less frequent resort to subterfuge, and for effort on the part of physicians to place themselves in a true light before their clients. The too common practice of speaking of the "bringing out of rashes," the "bringing of boils to a head," "clearing the blood of noxious humors," etc., was deplored, and stress was laid upon the value, in the way of educating the public, of a systematic endeavor on the part of physicians clearly to explain medical topics to their patients.

**Operative Treatment of High Myopia by Removal of the Crystalline Lens.**—Dr. Charles Stedman Bull, of New York, read a paper on this subject. He said that myopia was fast becoming a public scourge, so much so that in the near future there would have to be a new standard of requirements for entrance to our schools. The speaker pleaded for an earlier and more careful examination of the eyes of school children, and a stricter investigation into the whole subject of the hygiene of the school-room. This should embrace an inquiry into the best height of desks for children of a certain stature, the best methods of lighting and ventilation, the proper length of the sessions, and the frequency of intermissions. In regard to the special operative procedure under consideration, Dr. Bull stated that its advocates claimed that the eye, deprived of its lens, became either slightly myopic or hypermetropic; the retinal images were larger, and therefore there was greater visual acuity, and the excessive efforts at convergence were suppressed, and the congestive phenomena were made to disappear. The speaker indorsed Dr. Knapp's attitude regarding the operation, viz., "The real value of this treatment of myopia would be recognized when the period of its boom had been past." The ideal effect would be a post-operative myopia of only two diopters, in which no glasses would be needed for near work. Dr. Bull said that his own experience with this treatment had been extremely limited, and hence his conclusions were largely theoretical. The age and occupation, and the necessary demands upon the eyes, should be considered. A careful ophthalmoscopic examination of the fundus should be made, under atropine mydriasis, with special reference to the state of the blood-vessels of the retina and choroid, especially in the equatorial region. A careful examination of the visual field should be made with a perimeter; and finally the tension of the eye should be tested, and if there was a minus tension there would be ground for the suspicion that serious disease of the fundus was present. The possible dangers were: (1) Intraocular hemorrhage, from rupture of choroidal or retinal vessels; (2) detachment of the retina, with or without hemorrhage; (3) secondary glaucomatous symptoms, all resulting from the swelling of the lens after laceration of the capsule; (4) infection of the corneal wound or iris, or both. The third danger need give no uneasiness, as the symptoms would speedily subside. The danger of infection was now exceedingly slight. A possible complication was the anterior adhesion of the iris to the point of entrance of the needle. Again, the iris might be incarcerated in the wound, or prolapsed. The contraindications were: (1) Extensive degenerative changes in the retina or choroid, in the region of the macula; (2) detachment of the retina already existing; (3) opacities in the vitreous indicating more or less extensive disease of the choroid and blood-vessels; (4) previous loss of one eye from whatever cause; (5) decided loss of transparency of the cornea; (6) any form of contagious conjunctivitis, particularly trachoma; (7) advanced age of the patient; (8) myopia of less than twelve diopters. The indications for the operation were: (1) The degree of visual acuity actually existing at the time—if not sufficient for the social needs of the patient, the operation was indicated first on one eye and then on the other, if there were no contraindications; (2) if there was unmistakable evidence of rapid increase in the nearsightedness, and if the myopia amounted to twelve diopters or more. Dr. Bull said that the vision of all myopes was undoubtedly improved by operation, and continued to increase for six months afterward. The wearing of moderate convex glasses after operation was much less annoying to the patient than the wearing of strong convex glasses before the operation. In conclusion, the author laid special stress on the fact that the operation should not be done under any circumstances if there were present any degenerative changes in the retina or choroid in the region of the macula, for, in the face of such disease in this locality, the operation would inevitably lead to retinal intraocular hemorrhage, and to destruction of the eye. Moreover, the operation should never be done in one time and one motion. The younger the patient the better the result.

**Progress of the Science and Art of Obstetrics.**—Dr. Florence O. Donohue, of Syracuse, read this paper. He stated that science had waited sixteen centuries after the Christian era for the discovery of that most useful instrument, the obstetric forceps. The greatest gain had come from the discovery and partial development of the principles of antisepsis, and in proportion to the recognition of the part played by germs in disease and the success of the efforts to exclude them, would be the improvement in the death rate from childbirth for which we all hoped. The very blood of the parturient was different from that of other human beings. Semmelweiss had been the first to regard puerperal fever as a wound infection. The speaker claimed that midwifery was further advanced toward scientific perfection than any other branch of medicine. The most recent important advance was in Cæsarean section. Thus, a few years ago the attendant mortality had been estimated to be ninety per cent.; now this operation showed a mortality of nine per cent. This success was not due to the skill of one operator, but was computed from a series of operators. It was largely due to the adoption of Lembert's intestinal suture for closing the uterine wound. The writer contended that the present low rate of mortality following childbirth was not only due to our knowledge of the part played by germs, and to their successful exclusion, but also to the early use of forceps in prolonged labor; to the more frequent induction of premature labor in cases of contracted pelves, the modern treatment of eclampsia, and the improved treatment, prophylactic and actual, of post-partum hemorrhage. The percentage of deaths from Cæsarean section, the speaker said, was so small at present that he believed this operation, or the more frequent induction of premature labor in cases of contracted pelves, should be substituted for craniotomy.

Dr. William E. Swan, of Saratoga Springs, spoke of the different germs causing puerperal infection, and advised resorting to bacteriological diagnosis and relying largely on this in deciding upon the plan of treatment to be adopted. Vaginal examinations should be abstained from as far as possible; when necessary, the same preparations were in order as for a major surgical operation.

Dr. Finder, of Troy, thought it would be better to institute treatment, in a case of puerperal infection, before rather than after bacteriological examination, because time was precious, and, after all, the particular kind of germ infection was not, in his opinion, of great practical value.

Dr. Risch, of Kings County, said that the physician was not always responsible for the infection of

the puerperal woman; such infection might arise from the admission of air to the vagina. For this reason he advocated making the vaginal examination with one finger so as to allow of the labia closely hugging the examining finger.

**Impressions of the Work of the International Gynæcological Congress at Antwerp in August, 1899.**—Dr. A. Palmer Dudley, of New York, presented this report. He described in detail the work of the congress each day. As a result of a discussion on the treatment of uterine fibroids, the position was taken that the abdominal route for the surgical treatment of fibroid of the uterus was the proper one, in the majority of cases. On the third day a woman physician had exhibited under the microscope what he believed to be the first specimen ever shown of an early ovarian pregnancy. On the fifth day there had been an interesting and animated discussion on the indications for Cæsarean section, and comparing the true Cæsarean section with the Porro operation, with symphyseotomy, and with induction of premature labor. The conclusion reached by the disputants was, that, except in cases complicated by fibroid tumor, Cæsarean section was the only operation to be performed at the present day. Symphyseotomy was too uncertain. The consensus of opinion was that, at the present day, no man was justified in killing the child. It was gratifying to know that the only really original contribution to the congress had been conceded to be that of an American, whose work was yet in an experimental stage and not ready for publication. The one blot on the work of the congress was a surgical display with the aid of the cinematograph. It enabled the surgeon giving it to "play to the galleries" in a shameful though novel manner. Thus the display on the screen gave the impression that a hysterectomy had been done in five minutes, whereas it had really consumed one hour and a half. Perhaps the most disheartening thing in connection with this wretchedly unethical exhibition was the news that the exhibitor had avowed his intention of transporting his new advertising scheme to this side of the ocean.

**Some Practical Experience in Asepsis and Antisepsis in Obstetrics.**—Dr. Douglas Ayres, of Amsterdam, read a paper with this title. As an example of the importance of the subject reference was made to the records of the New York City health department from 1868 to 1886, showing that in this period of eighteen years thirty-three hundred and forty-two deaths had resulted from childbirth or diseases dependent thereon. The speaker said that asepsis was not enough in obstetric practice; antisepsis was required. The woman should be carefully instructed in the matter of personal cleanliness. In all cases of labor the physician should insist upon the cleansing of the external genitals by means of soap and water, and washing with corrosive-sublimate or carbolic-acid solution. The obstetrician should make few vaginal examinations, and before doing so should disinfect the hands and arms as for a surgical operation. It was convenient to have two flannel cases for the obstetric instruments, so that one would always be clean and ready for immediate use.

**Hydrorrhœa Gravidarum and Hydrosalpinx.**—Dr. Frederick S. Cowles, of Westbrook, Conn., read this paper. He said that it had been generally supposed that hydrorrhœa was due to the gradual accumulation and final discharge of an abnormal quantity of a fluid secreted by the uterine glands; but from a case that had come under his observation he was inclined to believe that it might, in some instances at least, be due to a discharge of fluid through a Fallopian tube, the seat of a hydrosalpinx. The condition was probably much more common than was generally supposed. Cases of supposed premature escape of water prior to parturition were probably to be explained by the existence of hydrorrhœa.

Dr. Risch remarked that it was important to differentiate, when possible, between intra- and extra-amniotic hydrorrhœa, for in the former speedy delivery was demanded if the child was viable, whereas in the latter there need be no such haste.

**A Brief Summary of the Indications for Operation upon the Stomach.**—Dr. Max Einhorn presented this communication. Regarding operations on the stomach in cases of malignant disease of this organ, the author took the ground that operation should be resorted to as early as possible, but in benign affections of the stomach he was in favor of postponing operation until satisfied that all other modes of treatment were ineffectual. The indications for gastrotomy and gastrostomy respectively were stated to be the following: For gastrotomy, simple incision in the stomach: (1) When an irregular and sharp foreign body had been swallowed; (2) if the body were too large to pass through the pylorus, and caused pain or vomiting; and (3) in rare instances for purposes of diagnosis. For gastrostomy the indications were: (1) When the passage of fluid or food into the stomach was arrested by a malignant growth; (2) when the obstruction was produced by the pressure of inoperable intrathoracic tumors; and (3) when a stricture produced by a benign growth would not yield to dilatation by the mouth; and (4) some cases of idiopathic dilatation of the œsophagus.

Dr. Delancey Rochester, of Buffalo, favored operation when, after a reasonable time, little or no improvement resulted from other treatment, in cases of benign tumor. In his opinion, divulsion of the pylorus should never be practised. While gastro-enterostomy was an excellent operation in cases of malignant disease of the pylorus, it had the disadvantage of interfering a good deal with duodenal digestion, and hence pyloroplasty seemed to be preferable.

Dr. Finder spoke of the great tolerance of the stomach to severe operations.

Dr. F. W. Higgins, of Cortland, suggested that death, occurring within twenty-four hours after an operation on the stomach, might be the result of shock following incidental traumatism to the great sympathetic plexus.

**The Value of Operative Treatment of Spina Bifida.**—Dr. W. B. Reid, of Oneida, read this paper, reporting an original method successfully pursued in one case for the closure of the cleft. The case was of that variety known as a meningocele. Daily aspiration of nine ounces of fluid had been practised for three days prior to the operation, with a view to lessening the chances of shock from sudden release of pressure on the brain and spinal cord. An incision had been made on either side of the centre of the sac, which had then been dissected out and excised close to the pedicle. The stump had been made to do duty as a plug, nicely fitting the cleft. A plaster jacket had then been applied and kept on for fourteen weeks. The wound had healed primarily. This was two years ago, and the child had remained well.

Dr. H. O. Marcy referred to a case of spina bifida of large size, upon which he had successfully operated, closing the opening by doing a hernia operation.

**Some Cutaneous Manifestations of Syphilis and Other Affections of the Skin.**—Dr. John A. Fordyce, of New York, gave a lantern-slide exhibition of a most instructive series of cases of this kind.

**Discussion: Does the Present Method of Securing Expert Testimony Subserve the Ends of Justice?**—Hon. Willard Bartlett, justice of the supreme court, was the first speaker. He defined, for the purposes of this discussion, medical expert testimony to be "the sworn opinions of persons specially skilled in medicine and surgery on any point in their science

or art which is in question in a proceeding in a court of justice." The speaker took the ground that one great reason for the cry against the partisan character of medical expert testimony was to be found in the frequency with which such experts assumed the double rôle of expert witness and special adviser to counsel. The following reforms had been suggested: (1) The appointment of a committee of experts, in insanity cases, to examine the person alleged to be insane, before the trial, and make a report at the trial, all the members being in attendance for cross-examination; (2) that in cases requiring expert evidence, the experts should testify without compensation except the fee to be fixed and paid by the State; (3) the relegation of all matters for expert testimony to a commission of experts; (4) the appointment of expert witnesses, who may qualify for the purpose, without consultation with the litigants or their counsel, compensation being furnished by the county in which the trial occurs; (5) the enactment of a statutory prohibition against receiving any expert evidence from a witness who has been paid, or expects to be paid, by either party, and who receives only the insignificant sum provided by law for ordinary attendance on court. Judge Bartlett said that it was impossible, without changing our whole constitutional system of government, to bring into effect any plan which would prevent litigants in an action at law from calling expert witnesses whom they may select. In his opinion no effort at reform would succeed that did not leave the expert liable to a most searching cross-examination. A good doctor had no occasion to fear it and seldom suffered under it, but the bad doctor could hardly fear it too much. He was convinced that the bench, the bar, and the common people were all opposed to the substitution of a jury of experts for the common-law jury. It was entirely possible for the doctors of this State to discourage the practice of acting as both adviser to counsel and as expert witness. The remedy that he would suggest was an amendment of the medical code of ethics, regulating the course to be pursued by the medical expert.

Hon. Joseph L. Daly, formerly justice of the supreme court, took up the discussion at this point. He could not see why it was any more harmful for medical experts to be remunerated by the party calling them than for the legal expert, familiarly known as "counsel," to receive like compensation.

Charlton T. Lewis, LL.D., continued the discussion. He boldly declared that the fault was not in the profession of law or medicine, but in the system of jurisprudence. That system sought an average justice, not an ideal exactness; it was utterly incapable of eliciting scientific truth or solving any problem in which science was a determining factor. It would be wholly in accord with our traditional system and with the methods approved by all experience, if the laws of nature and the principles of science applicable in each controversy were formulated by an expert tribunal independently of controversy, and then accepted by both court and jury. The present procedures connected with the taking of medical expert evidence were characterized as nothing better than traditional superstitions. The ideal plan would be a complete separation of tribunals, so that expert evidence should be heard only by an independent scientific court. The merit of the plan, by which counsel occasionally left the selection of an expert to the judge and agreed to accept the result, appeared to him so great that he would assert that it was the most direct and effective way to the truth. Of course, any change for the better must be made very gradually and tentatively.

William A. Purrington, Esq., was the next speaker. He stated that many supposed instances of perjury on the part of witnesses were, in his opinion, nothing more than inaccuracies arising from a frame of mind induced by "suggestion" practised by the examining counsel. Judges were really experts, who delivered their opinions dogmatically, and they possessed binding force until set aside by some judge higher up in the forum. Although judicial decisions differed widely, no one accused the judges of incompetency or dishonesty.

---

*Second Day—Wednesday, October 25th.*

**The Necessity for State Aid in the Treatment of Pulmonary Tuberculosis.**—Dr. George W. Goler, of Rochester, read this paper. He stated that it was generally admitted that thirteen thousand persons died in New York State annually from tuberculosis. Assuming the average life of the consumptive to be four years, there would be fifty thousand cases of tuberculosis always present in this State. According to the lowest estimate a cure could be effected in twenty per cent. of the cases. For the suppression of diseases more tragic in their course than consumption the State spent large sums of money annually. The average duration of life in the insane person, after admission to hospital, is twelve years, and the average annual cost is $186, thus making the total cost for each insane person $2,232. Of the epileptic population not over six per cent. were cured. Special sanatoria should be provided by the State for the cure of tuberculosis, and in them seventy per cent. of cures should be realized.

**Sanatorium Treatment at Home for Patients Suffering from Pulmonary Tuberculosis.**—Dr. S. A. Knopf, of New York, read this paper. In it he reviewed the essential features of the treatment, as carried on in special institutions in this country and abroad, and described how, with simple apparatus, much could be accomplished at the patient's home. The treatment of the consumptive poor was best carried on in State sanatoria.

Dr. Delancey Rochester spoke of the difficulty in making patients wear the flask or use paper handkerchiefs properly. The patient should take milk freely, but it was best to order it taken at a certain time—preferably three hours and a half after an ordinary meal. It was also important that the patient should take water freely. In using cold affusions, he had found it an advantage to substitute for the pitcher a fountain syringe with a large spray nozzle. State sanatoria were needed for the incipient cases occurring among the poor; the more advanced cases could be sufficiently well treated in county hospitals.

Dr. Didama took exception to the prevailing notion about the hereditary transmission of a "tuberculous predisposition." He said that only twenty-seven persons out of every hundred were even distantly related to consumptives, and these did not inherit a "tendency" any more than any one else having a bad constitution. A child kissed by a tuberculous mother was liable to contract tuberculosis of the bowel.

Dr. W. E. Finder said that tuberculosis was, to his knowledge, contracted by patients and nurses in general hospitals. The public sadly needed education on the subject of tuberculosis, and it was most rational to begin by teaching the school children.

Dr. Washburn put in a plea for the "farm colony" in connection with the State sanatorium, and then introduced the following resolution, which was adopted:

*Resolved*, That the New York State Medical Association approve of the State establishing sanatoria for the care of consumptives, and that it is the sense of this association that sanatoria for the incipient cases should be conducted in connection with the farm colony.

Dr. Bernard Cohen, of Buffalo, suggested that if the profession really desired to secure such legislation, the assistance and influence of the rural physician should be enlisted.

**Reopening the Abdomen for Post-Operative Septic Peritonitis, with Report of Cases.**—Dr. C. C. Frederick, of Buffalo, read this paper. He pointed out the danger of drainage and its needlessness. He had great faith in the efficacy of complete hæmostasis, thorough cleansing of the peritoneal cavity, and in filling this cavity with saline solution, thus diluting the infection and augmenting the absorbing surface.

Dr. Frederick Holme Wiggin, of New York, said that if the author had not used drainage, the result might have been better. The use of the drainage tube, in a case like the one referred to, was futile; moreover, it opened up new channels for infection. Even in bad septic cases the prospect for recovery would be better if no drainage was employed and if the surgeon relied solely on the intravenous or intracellular injection of saline solution. This procedure powerfully excited the emunctories and so favored the elimination of septic material. The speaker favored disinfection of the peritoneal cavity with hydrogen peroxide, followed by a free use of decinorml salt solution.

Dr. H. O. Marcy, of Boston, said that he hesitated to make use of hydrogen peroxide in the peritoneal cavity, believing that it oftentimes served to diffuse the infection. He did, however, use with much confidence a 1 : 1,000 solution of bichloride, following it with plenty of saline solution. He had never noted any bad effect from this procedure, but believed that it had been the means of saving life.

**Morphinism among Physicians.**—Dr. T. D. Crothers, of Hartford, Conn., presented a communication with this title. He said that morphinism was the modern disease of physicians. After an extended study of the subject and the collection of statistics, the estimate had been made that ten per cent. of all medical men used morphine. The causes were complex, and arose from conditions of living and surroundings, as well as from neurotic defects. Personal self-treatment was especially disastrous. In morphinism there was profound psychical and physical poisoning, and a cure was not effected by the mere removal of the drug.

Dr. Leroy J. Brooks, of Norwich, said that he personally knew of twelve cases occurring among physicians in his county; four had the morphine, cocaine, and whiskey habits, four had the morphine and cocaine habits, and four the morphine and whiskey habits. Only three out of the twelve were over fifty years of age. There was a special temptation for rural practitioners to fall into such habits.

**Albuminuria: Its Prognostic Value in Chronic Nephritis.**—Dr. Charles Alling Tuttle, of New Haven, Conn., read this paper. He declared that urinary examinations, as ordinarily made in the physician's office, had but little value, and that the toxicity of the urine often afforded the best and safest means of diagnosis. Chronic interstitial nephritis, he averred, could exist without albuminuria, casts, or the usual clinical symptoms of kidney impairment, and albuminuria of measurable amount and renal casts might be present and yet the health of the individual be unimpaired throughout many years. The propositions supported by the essayist were: (1) Bright's disease may exist without albumin and casts; (2) albumin and casts may be found in normal urine; (3) given a case of chronic Bright's disease with albuminuria, its constancy or its amount had no prognostic significance.

**Curability of Epilepsy, and How It may be Accomplished.**—Dr. William P. Spratling, superintendent of the Craig Colony for epileptics, presented this paper. He said that the early treatment of reflex epileptic phenomena was of great importance. Many cases of nocturnal epilepsy passed unrecognized until far advanced. Out of four hundred and eighty-five persons admitted to the Craig Colony eighty-three per cent. had developed the disease before the age of twenty years, and twenty out of a series of one hundred and forty-five had given manifestations of the disease as early as the sixth month of life. Before making a prognosis or instituting treatment it was well most carefully to consider the ancestry. The author objected to giving young subjects drugs, the chief action of which was to suppress the convulsive phenomena, for such treatment not only was liable to mask the diesase, but experience had shown that it would seriously impair the digestive and assimilative functions. He had yet to see a single case in which the use of the bromides had cured the disease, although it had often suppressed the convulsive phenomena for long periods. In his opinion, it was wrong to operate upon an epileptic brain after an injury and years of convulsive seizures. Great stress was laid on a study of the aura, which was designated as the "sign-post" to the treatment. The colony plan allowed of the entire and much-needed control of all the habits of life of the individual. The diet should be simple and nutritious, and taken in moderate quantity; tobacco should be indulged in moderately, and the whole mode of life should be completely though gradually changed.

**Discussion on Typhoid Fever—The Advance in Our Knowledge of Typhoid Fever.**—Dr. Herman M. Biggs, of New York, opened the discussion with a consideration of the above topic. He said that the first great step in advance had been made through the writings of Shattuck and Flint in this country, and of Sir William Jenner in England. They had made possible the clinical differentiation of typhoid from typhus fever, and had marked the beginning of the first period—from 1850 to 1880. The second period had been ushered in in 1880 by Eberth's discovery of the typhoid bacillus. The third period extended from that year to the present time; and in this had the greatest advances been made. We could no longer speak properly of typhoid fever as "enteric fever." In the majority of cases the typhoid bacilli made their way into the circulation at some stage of the disease, as shown by the rose-colored spots and by the demonstration of these organisms in the blood. A negative result from the Widal test could not be regarded as having much significance, but a positive reaction might be looked upon as almost conclusive proof of the presence of typhoid fever. Nearly all observers were agreed as to the nearly constant presence, in the early stages, of the diazo reaction of Ehrlich. It might be present between the third and seventh days of the disease—in other words, before the Widal reaction could be obtained, and prior to the time when the clinical symptoms were at all distinctive. Unfortunately it was frequently present also in general miliary tuberculosis, an affection frequently mistaken for typhoid fever. Regarding the use of preventive inoculations, the statement was made that, of two hundred persons at the Maidstone asylum, ninety-five had been inoculated, and none of these had contracted typhoid fever, whereas of one hundred who had refused this treatment nineteen had become ill with the disease. These inoculations had been made with attenuated and sterilized cultures. The injection was followed by swelling and tenderness at the site of the injection, and by a mild febrile reaction. By such treatment the blood acquired the agglutinative property present in persons suffering from typhoid fever.

**Bacteriology of Typhoid Fever.**—Dr. W. H. Park, of New York, treated of this topic. He said that the infective material was found chiefly in the discharges from the sick—in the fæces and urine principally. The length of time the bacilli remained in the fæces was very variable; sometimes it was only a few hours, but usually they did not disappear for several days. Typhoid bacilli could not usually be detected in water for more than fourteen days, and for

this reason, chiefly, examinations of water for typhoid bacilli had almost no practical value. A rather unique case of infection from ice had recently been reported. Typhoid fæces had been thrown upon the ice of a certain lake in January, and the disease had developed the following July only among the families supplied with that ice. We were coming more and more to look upon insects as carriers of disease. One or two observers had claimed to have found typhoid bacilli in the bodies of insects, and an experiment, repeatedly performed in the laboratory, was the infection of culture media by foot-tracks of flies. Typhoid bacilli were not found in the urine until the third week, or possibly much later, yet after this time they appeared in pure culture and in enormous numbers. They would often persist in the urine for weeks or months. A case of cystitis, therefore, developing shortly after an attack of typhoid fever should be suspected at once of being the result of typhoid infection. Disinfection of the urine should always be insisted upon and the patients warned of the great need for carefully disinfecting their urine and fæces for a number of weeks after convalescence from typhoid fever. The bacilli would disappear more rapidly under the administration of urotropin, in doses of gr. x. three times a day.

**Clinical Diagnosis of Typhoid Fever.**—Dr. William Osler, of Baltimore, considered this phase. He said that the diagnosis must always be founded on circumstantial evidence, and yet there were few diseases in which the diagnosis was so certain. In some cases of very short duration and mild type the Widal reaction was most useful. In severe cases death might occur even before the Widal reaction could be present, and in such it was quite possible that even at the autopsy the characteristic intestinal lesions would not be found. A large proportion presented no intestinal symptoms, but of thirty-five recent cases in his practice only four had shown distinct abdominal symptoms. The cerebrospinal, pulmonary, and renal localizations of the typhoid poison were exceedingly liable to confuse and mislead the diagnostician. It should be remembered that under the most favorable circumstances death might occur before a correct diagnosis could be made. A febrile typhoid, the speaker said, must be very rare, as he had never seen such a case. The occurrence of chills was, perhaps, the most frequent cause of an erroneous diagnosis. Chills were not infrequent in typhoid fever; they were so exceptionally the result of malaria that the latter should be the last thing thought of. The blood examination and the therapeutic test would decide. Dr. Osler said that he had been deeply impressed with the widespread belief among physicians that a diagnosis of malaria was often warranted, even in the face of a continued fever. This had been brought very forcibly to public notice by the action of the army surgeons in the late war in Cuba. Regarding the diagnosis of malaria, he would say to those practising in localities north of Mason and Dixon's line: (1) that intermittent fever which resists quinine was not of malarial origin; and (2) in these localities a continued fever was not due to malarial infection. He hoped that the pernicious term "typho-malarial" fever had been forever banished from our nomenclature. To the rural practitioner, without laboratory facilities, he would say: "Learn to suspect typhoid fever in every continued fever of six or seven days' duration, and especially if it proved resistant to quinine."

**Some Interesting Cases Illustrative of Typhoid.**—Dr. Edward G. Janeway, of New York, presented this contribution to the discussion. He said that it had been his lot to see three cases of tetany associated with typhoid fever. At times the mental state was so rapidly altered as to lead to the suspicion of insanity. There was often a marked suicidal tendency, which should lead the physician to take special precautions to prevent harm to the patient. The occurrence of herpes labialis in typhoid was so extremely rare that if it appeared he felt disposed to revise the diagnosis most carefully. A thick crop of petechiæ was prone to develop on the abdomen after the prolonged use of the ice-coil. He had known both appendicitis and sapræmia from retained menses to simulate typhoid.

**Statistics of Typhoid Fever at the Roosevelt Hospital for Ten Years.**—Dr. William H. Thomson, of New York, presented his statistics on typhoid fever for the period from September, 1889, to September, 1899. The total number was 368, 275 being males and 93 females. The total number of deaths was 25, or 6.8 per cent. Of those who died, 14, or 56 per cent., succumbed within a week after admission. Diarrhœa, developing after the first week in the hospital, was reported in only 8.7 per cent., and in the majority of these it was not very severe. This comparative rarity of diarrhœa he attributed, not to a change in the type of the disease, but to a change in diet, these patients not being fed on beef-tea as was formerly the routine. Tympanites had been very common among the soldiers returned from Cuba, but excluding these cases, it was noted in only 11 per cent. In 321 cases there had been no delirium. Pneumonia had occurred in 7 per cent., and bronchitis in 8 per cent. Phlebitis had been present in 7 cases. Relapses had occurred in 55 cases, or 15 per cent. The treatment had consisted in the use of a purge of calomel and jalap every third night, up to the close of the second week. Equal parts of milk and lime-water was the exclusive diet until the end of the fourth week. He also used pepsin to aid the enfeebled digestion. Gr. x. each of pepsin and bismuth were given every three hours. As soon as the tip of the tongue became dry ℥ x.–xx. of spirits of turpentine were given every three hours. To combat the general toxæmia, the speaker said, he knew of nothing equal to the general cool bath. It was employed as soon as the temperature reached 103° F., and active friction was kept up during the bath. He had found that there was less depression and a more prolonged antipyretic effect from the artificial Nauheim baths. Rectal irrigations with saline solution had been used with the object of increasing elimination.

**Typhoid Fever in the Massachusetts Genelar Hospital during the Past Fifty Years.**—Dr. Reginald Fitz, of Boston, contributed this paper, which was largely a historical sketch. The mortality rate, by decades, was as follows: For 1839–49, 11.1 per cent.; 1849–59, 15 per cent.; 1859–69, 15.9 per cent.; 1869–79, 16.6 per cent.; 1879–89, 14.7 per cent.; 1889–99, 13.5 per cent. From 1839 to 1869 a liquid farinaceous diet was in vogue; from 1879 to 1889 it was chiefly liquid, beef-tea and the like; from 1889 to 1899 milk had been the chief diet. The mortality rates for these three periods were 14.1 per cent., 16.6 per cent., and 14.6 per cent. respectively. Baths had been used since 1873, and since 1888 sponge and tub baths at a temperature of 65° F. had been frequently given. His conclusions were: (1) The treatment of typhoid fever does not now differ materially from the principles laid down in 1839; (2) the average mortality has not changed since the days of such active treatment as purgation and venesection; (3) intestinal hemorrhage, perforation, and relapse are quite as frequent now as they were at any time; (4) a considerable variety of diet may be permitted, without detriment, and with possible benefit to the patient.

**Some Phases of Typhoid Fever as Seen in Bellevue Hospital.**—Dr. A. A. Smith, of New York, made this contribution. The statistics were, for the most part, based on 87 cases, as from this number only could histories be obtained. Out of a total of 104 cases,

there were 10 deaths, or 9.6 per cent. Chills were present in 57 per cent., diarrhœa in 57 per cent., typhoid eruption in 77 per cent. Of the 59 cases examined for the Widal and for the diazo reactions, the former was present in 82 per cent. and the latter in 7.4 per cent. Relapse occurred in 9 per cent.; all of these patients recovered. In the whole series, there had been only one case of nephritis. In five cases the plasmodium malariæ had been demonstrated during convalescence. The highest temperature recorded was 106.6° F., and that case proved fatal. One patient had died of intestinal perforation, as shown by autopsy, on the twenty-eighth day. Regarding diet, he was more than timid about the resumption of solid food, and made it a rule in his wards that it should not be given for eight or nine days after the temperature had permanently reached the normal.

**Typhoid Fever in Children.**—Dr. Abraham Jacobi, of New York, read this paper. He said that the absence of high temperature was worthy of note. General peritonitis was very uncommon. In certain epidemics he had found intestinal hemorrhage very frequent and severe. The food should be exclusively liquid until the temperature had been normal for ten days. A few drops of dilute hydrochloric acid, in a glass of water, made a useful and pleasant drink. The lips and tongue should be kept clean. When the tongue was dry and fissured, one or two applications should be made with a camel's-hair brush dipped in a one- or two-per-cent. solution of nitrate of silver. The posture in bed should be changed from time to time to avoid hypostatic congestion. The bowel should be irrigated frequently with water at 95° or 100° F. Internally, bismuth, sulphocarbolate of zinc, and salol were indicated. Stupor and coma should be combated by cold affusions while the body was immersed in water at 95° F. Antipyrin was perhaps the safest of the antipyretic drugs, but baths were better because of their stimulating action on the nervous system.

**The Local, Non-Surgical Treatment of the Intestinal Tract in Typhoid Fever.**—Dr. De Lancey Rochester, of Buffalo, presented this paper. He called attention to the importance of cleansing the mouth; if this was done sordes would be unknown. There was no evidence to prove the potency of remedies designed to destroy the specific bacilli. He strongly favored the use of calomel, at intervals of four to six days, in doses sufficient to produce from two to four stools daily. Systematically repeated irrigations of the colon were most beneficial.

**Treatment of Perforation of the Bowel in Typhoid Fever.**—Dr. W. W. Keen, of Philadelphia, contributed this paper. He stated that from 1884 to 1898 eighty-three cases had been operated on, with a resultant recovery rate of 19.3 per cent. From the beginning of last year up to the present time there had been sixty-seven additional cases operated on with a recovery of 26.9 per cent. He favored operating on practically every case of perforation unless the general condition was such as to make the case evidently hopeless. No age was a barrier, though it considerably influenced the recovery rate. Under fifteen years the percentage of recoveries was 50; from fifteen to twenty-five years it was 8.1 per cent.; from twenty to thirty-five years it was 25.6 per cent., and over thirty-five years it was 28.5 per cent. The best time for operation was not during the immediate primary shock, but in the second twelve hours after perforation, all things being considered. The operation should, of course, be done as soon as possible after perforation, but no prudent surgeon would operate during profound shock. During the first eight hours the chances for recovery were one-third of those which obtained during the remainder of the first twenty-four hours. The most important advance in technique was the substitution of local cocaine anæsthesia for a general anæsthetic. This had been first proposed by Cushing. The perforation, when found, should be sutured without paring, Halsted's mattress suture being used. Drainage would usually be required; though it was not improbable that better results might ensue from filling the abdominal cavity with salt solution and closing the wound.

**Eye Complications in Typhoid Fever.**—Dr. A. T. Hubbell, of Buffalo, made a few remarks on this subject. He said that catarrhal conjunctivitis and lacerations of the cornea were especially common complications of typhoid fever. The other principal eye complications were: retinal hemorrhages, accumulations of pus in the anterior chamber, suppuration of the deeper structures, iritis, choroiditis, opacities of the vitreous humor, opacity of the crystalline lens, neuritis and optic-nerve atrophy, embolism of the central retinal artery, orbital cellulitis, thrombosis of the orbital vessels, and paralysis of the extra- and intra-ocular muscles. Fortunately all of these complications were rare, and were easily diagnosticated.

---

*Third Day—Thursday, October 26th.*

**Officers Elected.**—*President*, Dr. E. D. Ferguson, of Troy. *Vice-Presidents*, Dr. Charles H. Glidden, of Little Falls; Dr. J. M. Farrington, of Binghamton; Dr. W. H. Thornton, of Buffalo; Dr. J. C. Bierwirth, of Brooklyn. *Secretary*, Dr. M. C. O'Brien, of New York. *Treasurer*, Dr. E. H. Squibb, of Brooklyn. *Members of Council*, Dr. Douglas Ayres, of Fort Plain; Dr. Charles Munger, of Knoxboro; Dr. E. M. Lyon, of Plattsburg; Dr. W. L. Ayer, of Owego; Dr. M. W. Townsend, of Bergen; Dr. Frederick Holme Wiggin, of New York. *At Large*, Dr. Joseph D. Bryant, of New York.

**Report of Committee on Quarantine.**—Dr. Stephen Smith, of this committee, described the three bills that had been before Congress, viz., the Spooner, the McCaffrey, and the Hepburn bills. The two latter, he said, proposed to impose new duties and functions on the Marine-Hospital service; the former advocated the establishment of a national commission in connection with the Treasury Department. The committee was continued.

**For Greater Uniformity in State Requirements for Medical Practice.**—On motion of Dr. E. D. Ferguson, the council was requested to appoint a committee of three, to confer with other societies, and take the requisite steps.

**Popular Instruction regarding Consumption.**—Steps were taken to secure the publication of a leaflet giving popular information on the best home treatment.

**Two Cases of Large Retained Hernia.**—Dr. Henry Orlando Marcy, of Boston, reported these cases to emphasize the fact that the fatal result had been brought about by interference with respiration and with the heart's action by causing excessive intra-abdominal pressure.

Dr. W. B. De Garmo, of New York, said that a paper of this kind was valuable at the present time as helping to settle the question as to where the line for operative cases should be drawn. Personally, he favored keeping these patients with large herniæ in bed for some time before operation, while efforts were made to reduce as much of the tumor as possible, thus accustoming the abdomen to this addition to its contents.

**The Admistration of Nitrous Oxide with Air or with Oxygen.**—Dr. Thomas L. Bennett, of New York, presented this communication. He said that the inhalation of nitrous oxide for a very short time was not infrequently followed by headache, dizziness, persistent nausea, or a tendency to yawn for twenty-four hours or more. He had been unable to find on

record any cases of disturbance of the heart, lungs, and kidneys, and from his own experience was sure that such results must be extremely rare. The prolonged administration of this agent was difficult, because the stages were exceedingly short and sharply marked. Deep narcosis was present after about one minute, and if air had been rigidly excluded there would also be marked asphyxia. On the other hand, if considerable air was admitted the patient would not pass quietly into deep narcosis, but would present marked signs of excitement; hence it was necessary to admit the air in definite quantities. Mixtures of nitrous oxide with pure oxygen afforded an ideal combination; and they were best made, in practice, by the use of Hewitt's apparatus. All changes in the proportions of the gases must be made gradually, as sudden changes were apt to interfere with the smoothness of the narcosis. This method undoubtedly afforded the safest and best form of nitrous-oxide anæsthesia, possessing all of its advantages and none of its disadvantages. It was practically impossible to move the patient after the anæsthesia had been started, without disturbing the narcosis. In a long administration of the mixed gases it was not uncommon to consume five dollars' worth of the gases. The abdomen was apt to remain rigid even when the narcosis was deep, and hence this method was ordinarily not well suited to abdominal operations. The greatest indications for this anæsthetic were to be found: (1) in those in whom ether or chloroform could not be used without special danger; (2) in operations so short as to render the effects of ether and chloroform out of proportion to the results; (3) in patients who had previously suffered extremely from ether or chloroform, and had in consequence a great dread of them. This anæsthetic agent had been found especially serviceable in the following cases: tooth extractions; incisions of abscesses and sinuses or division of strictures; curettings of various kinds; stretching in orthopedic cases; breaking up adhesions in joints; anal dilatation; removal of tonsils; doing major dressings; in the aged and in those presenting lesions of the heart and kidneys.

Dr. Golden said that he was positive that the degree of cyanosis depended almost entirely on the experience and skill of the administrator. The longest period that he had maintained narcosis with gas had been two hours, and with the mixture of gas and oxygen one hour and a half.

Dr. Delancey Rochester said that in most general hospitals it would be difficult to find a sufficiently experienced administrator on the house staff, and in rural practice it was hard to procure the gases.

*(To be Continued.)*

---

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, October 16, 1899.*

Frederick Holme Wiggin, M.D., President.

**A Family of Gall-Stone Sufferers.**—Dr. Carl Beck presented four members of one family, all of whom had suffered from gall stones. There were ten members in all in this family who had suffered from this disease, three of the others being now alive and three dead. One of those presented was a woman whose case was unique; it was the only one, Dr. Beck said, reported in the literature in which a gall stone had been removed from the left side of the body. This was because the woman had a transposition of the viscera. In the sixth intercostal space the liver could be easily palpated; the stomach was on the right side; the vermiform appendix was on the left. Skiagraphs were exhibited to prove that the heart and other viscera ordinarily on the right side were on the left in this person. The gall stone was quite large, and consisted of four different portions. The second patient presented was the sister of the first one. She had been operated upon for gall stones a short time ago. The symptoms had resembled very closely those of appendicitis. The gall bladder had reached down as far as the iliac fossa, and felt like a thickened band, not unlike an appendix. This had been because the several stones had arranged themselves one above the other in a linear manner. The third patient presented was the mother of the other two. She was seventy-two years of age, and had not yet been operated upon. In this case he had succeeded in getting a distinct picture of the gall stones on a photographic plate by means of the Roentgen rays. Ever since March, 1896, he had made it a rule to skiagraph every case of suspected cholelithiasis coming under his observation, and yet, although he had made use of the very best apparatus, he had not succeeded before this in securing the desired picture. In this woman a distinct tumor in the region of the gall bladder could be felt, and the history pointed plainly to cholelithiasis. For the past forty years she had suffered at intervals from what she called "stomach cramps," but there had never been any jaundice.

**Case of Spastic Spinal Paralysis.**—Dr. E. Gaillard Mason presented this case, a child, the youngest of seven children. It had been born by a breech presentation, but until six months old had been apparently like other children. When three months old an abscess had developed on the side of the neck, and had discharged for three months. Subsequently it had been noticed that the child was stiff, and did not walk properly. Latterly he had been improving. The points of interest were the fact that the paralysis had begun at a very early period, and that there had been decided improvement irrespective of any mode of treatment. The symptoms were the peculiar bed-spring gait, the exaggerated knee-jerk and triceps jerk, and the ankle clonus. There had been absolutely no impairment of sensation and no bladder or rectal symptoms. Up to two years ago he had been unable to walk at all; now he could put the foot down on the floor.

Dr. W. M. Leszynsky said that it was very rare in either an adult or in a child to see a primary case of this kind; as a rule, spastic spinal paralysis was secondary to a brain lesion. In a case like this one he would be inclined to think of the so-called "Little's disease," or a lack of development in the pyramidal tract both in the brain and spinal cord. This could be determined only by prolonged examination and study.

Dr. M. C. O'Brien said that one was apt in such cases, when seen early in life, to give an unfavorable prognosis, yet it should be remembered that after the third or fourth year improvement might begin, largely through the vicarious action of the other muscles. Of late years the tendency in treatment had been to rely upon electricity and massage.

Dr. F. M. Nye said that in recent cases he was in favor of giving a course of iodide, and then resorting to electricity.

**New Galvano-Cautery Instrument for Hypertrophy of the Prostate.**—Dr. Robert Newman presented a new instrument for use in the Bottini method of treating hypertrophy of the prostate. The instrument was catheter-shaped, with a decidedly tapering beak. A tunnel was provided for use with a filiform guide in difficult cases. The galvano-caustic knife was fixed in the posterior part of the instrument, and by means of an adjusting screw the platinum burner could be projected to a greater or less degree. The connections with the battery were made through two separate and

insulated rods. As the burner alone was heated by the current it was perfectly feasible to dispense altogether with the usual water cooling-device.

Dr. L. Bolton Bangs said that he had not had an opportunity of examining the instrument, but he felt very doubtful, nevertheless, concerning its effect upon the prostate. He had tried the Bottini method, and fully agreed with Dr. Newman that one instrument would not be suitable for every case. His own experience had taught him to narrow the field for this method of treatment. Personally he believed that electricity was a very uncertain force, failing the physician often at the most unexpected times.

**Vaccination.**—Dr. David P. Austin read a paper on this subject. He said that the introduction of bovine virus had done away with one great objection to vaccine, *i.e.*, the possibility of infecting the person with syphilis, and it had nearly overcome the feeling that it might be responsible for the communication of tuberculosis. Mention was made of a case coming under his observation, of a youth of eleven years, who while suffering from scabies had been vaccinated. As a result of this there had been twenty or more pustules formed on the body in the various scratch marks. Dr. Austin said that in 1870 he had had a large experience as a vaccinator for the board of health. There had been scarcely a failure among the primary vaccinations, while in the second vaccinations the number of successes had been something under sixty per cent., and with the third vaccinations about thirty per cent. He had himself been vaccinated about fifty times, yet none had proved successful after the fourth. He favored adopting the plan in private practice of vaccinating people once a year until the immune condition had been established. That vaccination was not appreciated as it should be in our own country had been taught us by the melancholy lesson of our troops succumbing to smallpox at Manila. The speaker thought the probable reason our troops in the West Indies had not been so susceptible to the disease was that they had been, for the most part, recruited from the East and South, where the practice of early and especially repeated vaccination was common. In his opinion the troops should have been vaccinated at intervals of a month until the vaccinations had no longer been successful; in other words, until they had become immune. Ordinarily this immunity could be produced in a child at the end of five years, and if treated in this way they would be immune for the rest of their lives.

Dr. J. H. Huddleston said that there could not be any doubt regarding the necessity for revaccination, but he could hardly agree with the statement that a life immunity could be established. When the vaccination was properly performed with good vaccine, and it was not successful, this was only evidence that at the time the person was not susceptible to the disease, but how long the immunity conferred by a successful vaccination would last no one could tell in the individual case. Immunity was slow of development, usually requiring from ten to fourteen days. It lasted for a variable length of time. Cases had been reported of natural immunity, but it was doubtful whether such cases really existed. In several series, including one hundred thousand cases each, no such case of natural immunity had been encountered. The immunity produced by the disease vaccinia might last only a short time. There was a case on record in the institution on North Brother Island in which there had been a successful revaccination within six months after a successful vaccination. Cases evidencing even shorter immunity were on record.

**The Protection Afforded.**—Dr. Frank S. Fielder said that the literature seemed to show that it had been customary to vaccinate a child in infancy, and again when first coming to school, and that a very large number of these second vaccinations had been successful. Statistics also seemed to show that after a successful revaccination the duration of the immunity was very much longer, although not likely to last the rest of one's life. Among fifteen thousand cases on record the deaths from smallpox among vaccinated persons had been thirty-five per cent.; in those with one vaccination it had been 7.73 per cent.; in those with two scars 4.7 per cent., and in those with three vaccinations 1.95 per cent., while in those with four or more scars of vaccination it had been 0.55 per cent.; hence when there were several scars indicating successful revaccinations, the mortality from smallpox was comparatively low. At one time he had vaccinated ten school children, each one in four places. Each child had had a typical vaccination in all four spots. Eight months afterward he had gone to the institution and examined all of these children. All had had typical scars. He had then vaccinated all of these children with unimpeachable virus, and three of them had "taken" very well. An experienced physician in the health department had told him that it was much easier to revaccinate a person than it was to get the disease after a successful vaccination.

**Natural Immunity.**—The speaker went on to say that he was sceptical about the existence of natural immunity, and added that the greater one's experience in vaccinating with good virus, the more sceptical did one become on that point. However, one physician who had been among hundreds of cases of smallpox, and had been repeatedly vaccinated without result, had submitted to being vaccinated by Dr. Fielder in a number of places with virus that had been proved by clinical tests to be of excellent quality. The vaccinations had been unsuccessful, and the same result had followed a repetition of this experiment a few months later.

**The Scar an Untrustworthy Guide.**—On the subject of vaccination scars and what they signify, Dr. Fielder said that in a large number of cases of typical vaccinations with good virus he had visited the persons again after six months and had been surprised to find the large percentage showing scars which would be rated as "fair" or "poor." Only about thirty-three per cent. of these cases had exhibited what would be termed "good" scars. On the other hand he had known cases showing poor scars to be quite resistant to revaccination. From these considerations it was wise to conclude that the only way to be absolutely certain of immunity was to revaccinate again and again.

**Locality of Vaccination.**—Dr. Henry Illoway said that at one time he had vaccinated a child of five years with a virus of good reputation. In all this child had been vaccinated five times without success. He had then tried vaccinating it with some human lymph, and as a control had vaccinated the brother of eleven years and the sister of nine years. The vaccinations on the brother and sister had proved successful, but the first boy's vaccination had been a failure. About six months later he had vaccinated this boy on the leg instead of on the arm as previously, with the result that a typical vaccination had been secured. This had suggested to him the possibility that owing to local differences in the circulation certain parts of the body might be more susceptible than others. His experience had led him to feel that there entered into this interesting question what might be called the dosage for individual cases.

Dr. Austin closed the discussion. He cited the case of a boy fourteen years old who had been repeatedly vaccinated without success, and who had finally been successfully vaccinated when human lymph had been used. Since that time he had twice vaccinated

him successfully. In closing, he insisted upon the importance of a sufficient number of revaccinations.

**Notes on Urethral Catheterism, Catheters, and Bougies.**—Dr. John W. S. Gouley presented a paper with this title, but for lack of time read only portions of it. The author not only gave the history of the introduction of catheters and bougies, but described in detail many of the ancient instruments and their mode of manufacture. He advised physicians to decline purchasing any but the best silk-web catheters which, although nearly double the price of the lisle-thread or linen instruments, were the cheapest in the end, and moreover possessed the advantage of being disinfected by formaldehyde vapor without injury. The well-known silver prostatic catheter, with its extraordinary curve and length, seemed to him to have been intended for a urethral lacerator and prostatic plough, while that unhandy instrument of torture, the prostatic web catheter, he characterized as worse than useless. Web catheters should not be so thickly coated as to prevent the braid from being seen through the varnish. A point worth remembering was, that when it became necessary to retain a catheter in the urethra or bladder, the highest grade would not always be found the best, because such were more quickly infiltrated with urine and made to swell irregularly under the continuous action of the urine. The American commercial catheters, or "ten-cent catheters," would be found useful in many instances. Such a catheter could be repeatedly boiled without injury, and might be used as long as the surface of the instrument retained its smoothness. No catheter whose surface was fissured or roughened should be passed into the human urethra. He had used an American silk-web catheter three hundred times without affecting in the least the smoothness of its surface. Web catheters and rubber catheters were much injured by lubricating them with fats of all kinds, or with glycerin; hence it was better to use as a lubricant a preparation of non-irritating soap combined with mucilage. Both web and rubber catheters were liable to become hard and brittle in time, but this change could be greatly retarded by wrapping these instruments loosely in antiseptic gauze and keeping them straight in a tightly closed metal case or glass tube. When a false route rendered impossible the passage of ordinary instruments, Hey's method of procedure was often very satisfactory. This consisted in passing a silk-web catheter, No. 9 or 10 English, as far as, but not into, the mouth of the false route. This catheter was armed with a curved stiletto which was withdrawn at the same moment that the catheter was pushed toward the bladder with the other hand. This caused the instrument to over-ride the false route and enter the bladder. For the performance of catheterism the patient was usually placed in the recumbent position. The operator seated himself by the sufferer's left side for urethral, and by his right side for vesical, exploration. Exploration of the urethra for stricture was best made with soft, flexible, acorn-tipped web bougies, the metallic bulbous bougies not possessing sufficient delicacy and precision. When dilating catheterism was indicated, it was advisable to begin, in the case of narrow strictures, by the momentary insertion of flexible web bougies every second or third day, increasing the sizes until a No. 10 or 12 English could be inserted. After this conical steel sounds might be used, but not oftener than once a week, and seldom exceeding No. 15 English in size. It was hardly safe to permit patients living at a distance to make use of steel sounds; they should be taught to use a very soft, olive-tipped web bougie not larger in the shaft than No. 13. For autocatheterism the rubber "velvet-eyed" catheter was ordinarily the safest for general use, the chief drawback being that the patients were apt after a time to get too bold and careless in its use. When there were many false routes, and great difficulty was experienced in entering the bladder, the surgeon had at his disposal a most precious device—the invaginated catheter of Mercier. Strangely enough this instrument had not been apparently appreciated by the profession at its full value, yet it might be fairly stated that in ninety-five per cent. of cases of prostatic false routes this instrument could be successfully employed. It consists of a female portion—a thin-walled silver catheter—and a male portion—a flexible but firm gum catheter a little smaller than the male portion. The male part should be introduced into the female about as far as the eye of the latter, and then the instrument was passed down as far as the obstacle, and the point of the metallic part engaged in the false route. The male part was then to be projected, when it would override the false route, already blocked by the tip of the female part, and would pass on into the bladder. The female part could then be withdrawn, leaving the other in the bladder. In conclusion, Dr. Gouley expressed the earnest hope that every one essaying to make use of catheters and bougies would take as his motto the honeyed words of Civiale: "*doucement et lentement*"—gently and slowly.

Dr. L. Bolton Bangs said that the importance of great gentleness and delicacy of manipulation in the urethra had been impressed upon him as long ago as when he had been an interne in Bellevue Hospital. The most successful genito-urinary surgeon was he who employed the most delicacy and gentleness, and on this subject the reader of the paper was especially qualified to speak. Both surgeon and patient were unfortunately too apt to look upon the urethra as a mere water-pipe instead of as a very delicate part of the human organism.

Dr. Joseph D. Bryant spoke of the information he had gleaned in hospital regarding catheterism under the tutelage of Dr. Gouley. The first point, he said, which the general practitioner should bear in mind was the great need of cleanliness of the instruments and of the urethra to be catheterized. Another general rule was not to make use of a rigid catheter. He had known severe chills to follow the passage of instruments used with all the usual precautions against infection, and even where there had not been an escape of even a drop of blood on the withdrawal of the instrument. He was not prepared to state just what was the cause in all cases.

Dr. S. Alexander emphasized the importance of perfection of instruments and perfection of touch. He said that he had never been able to obtain with Mercier's invaginated catheter anything like as good results as from the use of the filiform bougie and the Gouley catheter—an instrument which the innate modesty of the reader of the paper had prevented him from mentioning.

Dr. Carl Beck said that urethral catheterism should always be looked upon as a surgical operation, and should be performed with all that this implied. For emergency practice it was well for the practitioner to carry with him a metallic catheter which could then be quickly sterilized by boiling. It had been proved that the urethra contained all sorts of micro-organisms, including pathogenic germs, and it was wholly impracticable to sterilize the urethra, yet it was advisable to inject some mild antiseptic, preferably a five-per-cent. solution of iodoform in glycerin.

Dr. Gouley closed the discussion.

The programme of the evening was completed by a memorial address on the late Dr. S. B. Wylie McLeod, delivered by Dr. John Shrady. His life and many good qualities were dwelt upon, and the prominent part that he had taken in the work of the association was recalled.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting October 19, 1899.*

WILLIAM H. THOMSON, M.D., PRESIDENT.

**Locomotor Ataxia.**—DR. C. L. DANA read a paper on this subject. He said that tabes was a systemic disease sharply limited to the nervous system, its effects outside of this system being secondary. It first attacked the posterior spinal roots. The spinal ganglionic cell with its central and peripheral processes formed the elementary neuron—the first and rudimentary seat of the disease. The fibres or neurons of these spinal ganglia developed at different periods of fœtal life. The pathological change of tabes affected serially only certain segments of the spinal cord, usually at first only the lumbar and dorsal. In accordance with the segment attacked one had different initial symptoms. Tabes was not an inflammation, but a primary atrophy attacking the master tissue itself, and was not due to a syphilitic or meningitic affection. The nature of this primary decay was not known, though it was probably a premature senility resulting from a congenital or acquired weakness, and, in part, from the action of a toxin upon them.

Etiology: If there was no syphilis there would be no tabes or no paresis—at least this was the common conviction of clinicians, although complete proof was lacking. There was a something which got into the system and ran its course unaffected by iodide and without presenting the usual symptoms of syphilis, and yet it terminated in tabes. During the preceding period an individual so infected gave none of the usual evidences of syphilis, and was capable of begetting healthy children. Possibly in this form of syphilitic infection there was some by-product or some double infection. Another factor in the causation of tabes was heredity, and still another was an overuse or an abuse of the spinal cord. According to his own experience, most tabetics were neuropathic; they were born with badly developed neurons. A person with sound ganglionic cells might have syphilis a dozen times, but he would not get tabes. It was possible that in some cases a combination of syphilitic infection with abuse of an organ might so weaken it as to give rise to degeneration. Many tabetics were persons who had been commercial travellers, or men who had worked hard or who had walked a great deal. Sailors, who walked very little, rarely had tabes. The speaker placed very little emphasis on alcohol as a cause of tabes. Sexual excess, smoking, and traumatism were likewise, in his estimation, factors of small importance.

Diagnosis: Tabes when developing in the usual and classical way was easily recognized by the lightning pains, the Argyll-Robertson pupil, and the loss of the knee jerk. The loss of the knee jerk with one other symptom would usually be sufficient for a probable diagnosis. The knee jerk was lost in tabes, in profound alcoholism, crural palsy, and temporarily after certain infectious diseases. In about ten per cent. of the cases, however, tabes had an anomalous beginning. Tabes might begin with severe rectal or vesical neuralgia. The most puzzling type was the neuralgic. Not rarely the diagnosis must be made upon the pains alone. In some of the earlier cases an ataxia could be discovered by careful tests. In early tabetics he had found the swaying movements very wide and jerky. Under normal conditions a person standing on the toes with the eyes closed would simply sway antero-posteriorly. Gastric crises not infrequently obscured the diagnosis, but the violence of the symptoms without obvious disease of the stomach would usually give a clew to the diagnosis. Occasionally tabes began with a slow and progressive atrophy of the optic nerve. Not infrequently tabes was complicated with manifestations of secondary syphilis, as shown by headaches, cranial nerve palsies, and by evidence of myelitis with paraplegia. He believed exudative or secondary syphilis was entirely different from tabes, though rather commonly associated with it. By proper treatment the syphilis could be relieved and still the patient would go on and develop a typical tabes or paresis. Laryngeal crises were, in very rare instances, observed in the early stages. The trouble could be surely recognized only by the finding of some stigma of tabes.

Treatment: In the early part of the disease the patient should be placed upon a rigorous antisyphilitic treatment for several weeks, and this should be repeated annually. In addition to small doses of mercury and the iodide, the patient often received additional medicinal treatment for arterial sclerosis. It had been alleged that tabes was not so severe as formerly, and so he made use of the antisyphilitic treatment, thinking that there was quite possibly a direct connection between the two. He believed it occasionally did good, and it apparently did no harm: hence neurologists generally had not had the courage to refuse this treatment even to persons who presented no evidence or history of syphilis. For some time past he had felt called upon to change the treatment just outlined. In the first and second stages of tabes he believed all persons giving a history of syphilis should receive a rigorous course of mercury and iodide. In many such cases the tabes came on quite suddenly: in others there was a good history of primary and secondary syphilis. Mercury should be given first, the patient being kept at home and, as far as possible, in bed. The best way was to use corrosive sublimate hypodermically in doses of gr. $\frac{1}{25}$ to $\frac{1}{20}$ twice daily, and this should be kept up for several weeks. The patient should also take gr. xxx. of iodide of potassium daily. After the mercurial course the doses of iodide of potassium should be rapidly increased up to about gr. cccl. a day. The person should be under treatment for about four weeks. The hypodermic injections of mercury were rather painful, and it was sometimes well to add cocaine to the solution of mercury. The patient should then have a course of tonics for about two months, and receive lukewarm baths daily, followed by cool affusion in many cases. During this period counter-irritation should be made to the spine by means of a cautery or by small blisters. The patient should be kept as much as possible at rest during this period of three months. The diet should be moderate and simple, but nothing was gained by an exclusive meat or vegetable diet. There was nothing to be gained from prohibiting the customary and moderate use of either alcohol or tobacco. When there was no history of secondary or tertiary syphilis, and not the slightest sign of nervous syphilis, he believed it to be utterly useless to employ the mercury and iodide treatment. He had never known it, in such cases, to modify the malady in any way. Instead, he would treat these degenerative cases as though they were getting prematurely old. They should be put at once on the bath and tonic regimen already described. A quiet, institutional life was what was most needed, as this alone would often, for a time at least, stop the progress of the malady. Galvanization along the spine, or general faradization, together with the internal use of small doses of silver, sometimes acted admirably, when used in addition to the measures already mentioned.

The Strychnine Treatment: A still better plan of treatment, in his estimation, was to put the patient to bed and give hypodermically rather large doses of strychnine and small doses of morphine. The dose should be very small at first, and very slowly and cautiously increased. For example, at first gr. $\frac{1}{60}$ at each dose, twice daily, should be given, and at the end of

the third week it should be increased to gr. $\frac{1}{2}\frac{1}{0}$ at each dose. These doses should be gradually reduced again until the treatment was stopped altogether at the end of six weeks. This course should be repeated three times a year. Strychnine was a useful but at the same time a dangerous drug, sometimes aggravating or causing a return of the pains. It should not be used in the acute and rapidly progressive cases. It was much more easily used when guarded with morphine. He had not seen any evidence that ergot, arsenic, aluminum, barium, or gold did any good. Hot baths were dangerous, and the best form of hydriatic treatment for tabes consisted in daily lukewarm baths for ten minutes at a time, sometimes followed by cool affusion. It was better, he thought, for the patients to have such treatment at home rather than to go to health resorts and meet other tabetics from whom they would learn about much of the misery in store for them. Recently a new method of applying nerve stretching had been brought to the notice of the profession, but he had not personally observed any special benefit from it further than mere symptomatic improvement. The method of treating locomotor ataxia devised by Fraenkel had been tried for a number of years, and had proved to be of some use. By this method the patient was carefully taught the use of his limbs by the aid of various mechanical devices. He had not seen much benefit from it, though it certainly afforded the patient a certain amount of amusement and recreation. In the third stage only symptomatic treatment was indicated. It should always be remembered that in a chronic malady like locomotor ataxia the mental attitude of the patient was exceedingly important, and that he who could best keep up the fight would do best in the end.

**Not Wholly a Systemic Disease.**—Dr. G. M. Hammond said that undoubtedly tabes might be in part a systemic disease, but he believed that it might exist alone without any systemic complications. He agreed with the view that tabes began in the nerve roots and the ganglia, but believed all of the symptoms might be present in the legs without the primary change occurring in the nerve roots. Excluding fractures and tumors pressing upon the posterior columns there might be connective-tissue diseases producing the symptoms of tabes. Thus multiple sclerosis might do it, or even sclerosis that was not multiple. In almost all cases of tabes syphilis seemed to be the cause, but he thought that in many instances the first change was a vascular one—a syphilitic disease of the lining of the blood-vessels, causing occlusion of their lumina and death of the nerve tracts. Antisyphilitic treatment seemed to him advisable; not that he had ever seen any case of tabes in which the symptoms had been improved by such treatment, but because he believed it had a tendency to prevent future degenerations, vascular disease, or changes in the neurons themselves. He did not agree with the author of the paper regarding the rest cure in tabes. In his opinion, the best way to promote vitality in an organ was to use it moderately. Though the change had been likened to senility, it was not senility. Senility was a normal change; that occurring in tabes was abnormal. He had never seen any benefit from applications of electricity to the cord, and did not believe that it ever arrested changes occurring in the cord. He approved of the hydropathic treatment, but failed to see the advantage of putting medicaments in the water of the bath, as the skin could not possibly absorb them. He favored using large doses of strychnine. He had given hypodermically as much as gr. $\frac{3}{4}$ at a dose without any toxic effect whatever, and with great benefit to the patient. He believed it acted by improving the nutrition of the diseased portions of the cord. If the Fraenkel method acted at all it did so by training the individual to use his muscles through the medium of the eyes. The patient's muscular sense was gone, and his tactile sense was interfered with, hence his muscles must be guided by the eye. For this reason the results of the treatment must depend largely upon the intelligence of the individual. Personally he had seen very little benefit from the method.

**Tabes Not a Spinal-Cord Disease.**—Dr. Joseph Collins said that tabes was not a disease of the spinal cord at all, and that the sooner this was understood the sooner would the profession have a clearer conception of the true nature of the disease. He was not inclined to think that neuropathy played such a conspicuous part in the development of tabes as was claimed by the author of the paper. In a study of one hundred cases he had found a decided neuropathic disposition in only ten per cent. If syphilis could be wiped from the face of the earth, tabes would go with it, for although it was not truly a syphilitic disease, it was intimately associated with it in a way not well understood. He was so sceptical regarding the value of antisyphilitic treatment in tabes that he never thought of putting his tabetics upon antisyphilitic remedies unless they gave a distinct history or presented evidence of this disease. He was confident that much harm was done tabetics by this very common routine and irrational treatment of tabes. All this simply meant that there was no adequate treatment of syphilis. The reason the tabes of to-day was not so severe as formerly was, that the profession had learned to diagnosticate the disease in its earlier stages.

The Fraenkel Treatment Valuable: The Fraenkel treatment was merely intended to make the patient more independent and better able to earn a living. He cited one case from his personal experience, that of a girl who had been enabled by this treatment again to earn her living by her former occupation of dancing.

**Pseudo-Tabes.**—Dr. B. Sachs said that if tabes dorsalis was not a spinal-cord disease it certainly did a great deal of harm to the spinal cord. Many cases appearing at first to be excellent examples of tabes dorsalis often turned out to be cerebro-spinal syphilis. He had previously called attention to the irregular development of the symptoms, and the coexistence of a large amount of paralysis with ataxia, the absolute immobility of the pupils and their irregular contour as points characterizing these cases of cerebro-spinal syphilis which simulate posterior spinal sclerosis.

Antisyphilitic Treatment should be Tried: He did not think as yet any physician could afford to neglect giving the antisyphilitic treatment a trial in all cases of supposed tabes. From his personal experience he was sure that such treatment brought about a favorable change in cases which he had diagnosticated as tabes.

Advocates Rest and the Fraenkel Treatment: He would subscribe to everything advocated in the paper regarding the rest treatment; it seemed to him perhaps the most valuable treatment for the earlier stages of the disease. In many of these earlier cases, if the patient was simply put to bed for three months without any other treatment whatever, he would be greatly benefited. There was experimental proof that exercise was calculated to bring about changes in the spinal cord very similar to those found in posterior spinal sclerosis. But more than this, experience had abundantly proven that rest was advantageous. It seemed to him that the reader of the paper had somewhat underrated the Fraenkel method. He had given it a personal trial during the past two years, and the result had pleased him. The patient was not particularly interested in whether or not his sensory neurons were improved: all that he cared was to be able to walk better. He had seen very great improvement in this respect, and as the method was learned so simply and

so easily, without any special apparatus or skill, every general practitioner should familiarize himself with it. The Fraenkel method could be advantageously combined with the rest treatment. On the whole, tabes was not a very unsatisfactory disease from the standpoint of the therapeutist, because so much could be done in the way of giving relief.

**Tabes Rare, though Syphilis Common, in Japan.**—Dr. M. Allen Starr thought that physicians were liable to take extreme opinions on medical topics. The question of syphilis in relation to tabes seemed to him to be still an open one. Although Erb had said that eighty-nine per cent. of his patients had had syphilis, he had been compelled to admit that the other eleven per cent. had not had it; therefore he would not subscribe to the statement which had been made, and which had so far not been challenged, that if syphilis was wiped off the face of the earth tabes would be unknown. In his own experience syphilis certainly had not entered into more than seventy per cent. of his cases; among his private patients syphilis had not been found in more than forty per cent. It should be borne in mind that in Japan syphilis was very prevalent, while tabes was almost unknown. This information he had obtained directly from two physicians who had an immense *clientèle*, and who saw there an enormous mass of clinical material. It had occurred to him that the Japanese practice of bathing in warm water two or three times a day might explain this comparative immunity from tabes. At autopsies on cases of tabes one usually failed to examine the peripheral branches, and it was not improbable that the degeneration might begin here. For this reason he thought any mode of living that kept the peripheral circulation in good condition would tend to prevent the development of tabes.

**Hydriatic Treatment most Useful:** This information also afforded a therapeutic hint of possible value. Personally he had seen much benefit from the use of baths, and indeed from any mode of treatment that improved the nutrition and the general circulation. He believed thoroughly in the rest treatment. He had not tried the strychnine treatment, because in almost every case in which he had given this drug to tabetics for other purposes it had resulted in an increase of the pain.

**Antisyphilitic Treatment Only in Selected Cases.**—Dr. W. M. Leszynsky said that for at least fifteen years he had examined every patient appearing before him for somatic signs or for a history of syphilis. He had found that many patients had not been benefited, but, on the other hand, that they had been made decidedly worse by antisyphilitic treatment. Even the cases of cerebro-spinal syphilis were not always benefited by such medication. He had had four patients under the Fraenkel treatment. Two of these had not been benefited at all, and, on the whole, the results had been quite disappointing. Fraenkel himself had stated that all cases of tabes were not well suited for this treatment. The method could hardly be carried out satisfactorily in actual practice without the services of an instructor.

**The Diagnosis.**—Dr. William H. Thomson called attention to the frequency of the visceral developments of tabes in the early stages of the disease, thus obscuring the diagnosis. Reference was made to a recent case of a woman in which the only symptom at first had been a severe and most obstinate flatulence, coming on suddenly in paroxysms at short intervals, and disappearing completely just as quickly. This history had at once aroused his suspicion of the existence of tabes. There was no evidence of ataxia. Many years before she had lost the sight of one eye by an iritis, evidently of syphilitic origin, and the other eye exhibited the Argyll-Robertson pupil. The rectal and vesical neuralgias were often the initial symptoms, and remained so for a considerable time.

Treat the Peripheral Nerves: For some years it had seemed to him that there was a special indication for attacking this disease from the periphery. He had treated it, therefore, by local applications to the anæsthetic or painful parts by compresses wet in an infusion of capsicum of the strength of one drachm to the pint. This had quite generally given relief, and had, in some instances, improved the symptoms. He was very partial to the application of the actual cautery to the spine. This was most conveniently done by heating a glass rod in an alcohol lamp and applying it along the spine in spots about three-quarters of an inch apart. For the relief of the severe pains he relied upon acetanilid given in combination with belladonna. He always insisted upon every tabetic patient taking cod-liver oil as steadily as possible. For those who could afford to buy the salts for the artificial Nauheim baths these would be found useful and beneficial. While all seemed to agree concerning the efficacy of the rest cure, it was most difficult to put in practice, because many of these patients were in active business, and were compelled to earn a livelihood. All tabetics having a rapid pulse seemed to be benefited by the administration of intestinal antiseptics.

Dr. Dana closed the discussion. He said that he had never seen a case of syphilitic pseudo-tabes, adopting the nomenclature of Dr. Sachs. Such cases were, to him, cases of exudative syphilis added to tabes. The Fraenkel treatment seemed to him useful, but like the rest cure it was difficult to apply, as so many of these tabetics had sufficiently active lives without such exercise. His statistics were very much like those presented by Dr. Starr, but he felt regarding them as many did regarding the theory of evolution, that it was most convincing in spite of certain missing links.

---

## SECTION ON MEDICINE.

*Stated Meeting, October 17, 1899.*

Louis Faugères Bishop, M.D., Chairman.

**Relation of the Physician to the State.**—Dr. Louis F. Bishop made some remarks on this subject, including the narration of a sad case in which, although the possibility of curing the consumption had been clearly demonstrated, the patient's slender means had at last placed all hope of such a happy termination beyond her grasp.

**State Care of Consumptives and the Massachusetts State Hospital for Tuberculosis.**—Dr. Alfred Meyer, of New York, opened the general discussion of this important topic (see page 613).

**Results in Massachusetts.**—Dr. Vincent Y. Bowditch, of Boston, was the next speaker. As one of the visiting physicians at the Massachusetts State Hospital for Tuberculosis he was naturally closely identified with this movement for the better care of consumptives. The work there this year had been done with an insufficient appropriation, a fact which should be borne in mind by other States when applying to their legislatures for aid. Not the least important of the results flowing from such an institution was the education of the public through the agency of the discharged patients. The number admitted to his service during the year ending in the present month, had been two hundred and eighteen, of whom one hundred and twenty-six had been discharged. Of the latter eleven had left the hospital in less than two weeks, so that they had practically received no treatment, and were, therefore, excluded from consideration. Of the remaining one hundred and fifteen cases, the total number receiving treatment, thirty-five, or a little over

thirty per cent., had been discharged as "arrested" cases. By this term he meant cases in which the symptoms of cough, expectoration, and fever had disappeared, and in which the appearance was that of a return to health, in spite of the persistence of certain physical signs of the disease in the chest. Those discharged as "slightly improved" numbered thirty-seven, while seventeen had been "markedly improved." Thirty-four had not shown improvement. Of thirty-four patients seen in the Sharon Sanatorium, near Boston, and followed for years afterward, five had died, and all of these had returned to their former occupations against advice. All of the rest were still alive and well. The speaker concluded his remarks by expressing the wish that he could infuse into his audience some of the enthusiasm which he felt in regard to this work.

**Death Rate from Tuberculosis Not Decreasing.**—Dr. John H. Pryor, of Buffalo, said that he had no doubt that there had been a large decrease in the number of deaths from tuberculosis in England. It had also been stated that there had recently been a decrease in the State of New York, and some of the most optimistic had even gone so far as to claim that by a natural process consumption would, in time, disappear from New York State. But if the death returns were carefully studied in a general way it would be found that the general death rate in this State had also diminished in a remarkable way, and that the death rate from tuberculosis had shared in this decrease, but that it had not decreased so rapidly as that of other infectious diseases. It was fair to assume, therefore, that this decrease was not, to any great extent, due to efforts at preventing the spread of the disease. Last year the death rate from consumption in this State had increased by three hundred and thirty-nine, and had increased so far in the present year that if this rate continued there would be in the year over one thousand deaths from consumption—probably the highest death rate ever known. This was in itself, it seemed to him, one of the strongest arguments for the establishment of State sanatoria.

State Prevention as well as State Sanatoria: We should not only establish these sanatoria, but we should secure the adoption of measures which would mean practically the State prevention of consumption. It would not do, in his opinion, to leave this part of the work to individual cities or counties. It was not wise for the State to spend money on the care of incipient cases of tuberculosis if proper steps were not taken by the State for the prevention of the disease. The instant one secured State care of the consumptive and sanatorium treatment there was ideal isolation, and this prevented, for the time being, progeny—a most important matter to the community.

The Poor Consumptive's Lot Growing Harder: Although for years it had been known that from fifty to seventy per cent. of cases of incipient tuberculosis were curable, the condition of the poor consumptive had not been made any better; on the contrary, it had been made harder by the increasing tendency of general hospitals to exclude such persons. So far as he knew, there was no other class of cases which did not receive aid from the State; these people died simply and solely because they were poor.

Dr. Pryor said that in 1896 he had endeavored to secure some action on the part of the legislature of New York State, but had received no encouragement. In 1897 he had had a resolution introduced, proposing the establishment of a commission to look into the question of establishing an Adirondack sanatorium. This resolution had been passed, and, for the first time, the State had appropriated money for the care of the tuberculous subject. Last year $200,000 had been asked for, and it had been constantly urged that several State sanatoria should be established. He was chiefly interested now, not in theoretical considerations, but as to whether or not any action would be taken.

The Cost Counted: The question of economy could be very easily answered by a due consideration of the loss to the community from the persons who became victims of this dread disease. If the State spent $10,000,000 a year, it would be spending only a small fraction of what it should spend—indeed, it was only a question of shifting the expenditure from one place to another.

The Solution of the Problem: He would recommend: (1) State prevention; (2) sanatoria supported by the State, because the work could not be properly done by cities or counties; and (3) the establishment near the cities of sanatoria for the treatment of advanced cases of tuberculosis.

**The Economic Side.**—Ex-Senator Dr. George W. Brush, of Brooklyn, was the next speaker. He said that he had had the honor of being the chairman of the first legislative committee appointed for the consideration of this subject. This committee had visited the various institutions of our own State, and also the newly finished State institution in Massachusetts. The committee had then reported in favor of the establishment of an Adirondack sanatorium in this State for the treatment of consumptives. The report had not been adopted, nor the appropriation made by the legislature, but it was expected to have this, or a similar resolution, ultimately adopted. The speaker said that the first duty of the government was the protection of the lives and health of its citizens. This was, in part, what we paid taxes for. It would seem to need no argument that active repressive measures should be taken to stay the ravages of a disease which numbered more than one hundred thousand among its victims in this country yearly; but the reason was that tuberculosis stole into our homes like a thief in the night, and laid its hands upon those nearest and dearest to us, and we had been wont to think that we were powerless to do anything. Our effort should be to prevent rather than to cure, and as this was a task too great for individual action, the State must and should intervene. The financial loss each year from this disease, direct and indirect, exceeded the expenses of the State government—a startling fact, but one which was none the less true. How far the State should go in the matter of the isolation of such cases must be left for future experience to settle. The dictates of self-preservation, as well as the economic side of this question, demanded that the State should make such provision as would properly protect its citizens from the ravages of this disease.

Physicians Must Push it Along: The scheme presented to the legislature last year included the establishment of State sanatoria for incipient cases, the expense to be borne by the county from which the person came, and the latter to be admitted only after proper examination and certification as to his condition. What was needed just now was a push all along the line, and certainly a most vigorous and telling impetus could be given by the profession of this great city, and particularly by the members of this Academy of Medicine.

**The Rôle of Auto-Infection.**—Dr. George Alfred Evans, of Brooklyn, said that about seven years ago he had been made a member of a committee of the Kings County Medical Society to obtain information on the best methods of limiting or preventing pulmonary tuberculosis. He had suggested at that time that an effort be made to secure the passage of a city ordinance prohibiting expectorating in the public conveyances. It had so happened that this recommendation of the committee was the only one that had not been

accepted and adopted by the Kings County Medical Society. Dr. Evans said that he had then made an effort through the health board and with the co-operation of the street-car companies, to have notices put up in the cars, prohibiting expectoration. It had been asserted that if auto-infection could be stopped, patients with pulmonary tuberculosis would recover of themselves, and this he believed to be true. The statement had also been made that if one could prevent the spread of the tuberculous process, that which already existed would recover spontaneously: hence it was auto-infection which killed. Climatic treatment had no more effect in stopping the tuberculous suppuration than the air of any particular place would have in arresting any other suppurative condition. In his opinion, the treatment should be totally different in those in whom softening had occurred from that in persons in whom the tubercle had not yet broken down.

**Mixed Infection and Hyperventilation.**—Dr. William H. Thomson continued the discussion. He stated that tubercle bacilli by themselves were not responsible for the fearful mortality found in pulmonary tuberculosis; it was because of the formidable alliance between the tubercle bacilli and the pus organisms. Twenty years ago he had been deeply interested in an article by Dr. Hanford Jones on what he termed "hyperventilation" as a means of treating cases of pyæmia. This was nothing more than having the patients kept practically in the open air both night and day, regardless of the state of the weather. The results of this treatment had been most striking. In pulmonary tuberculosis the physician had to deal not only with tuberculosis but with chronic pyæmia. The sick poor could not be brought effectively in contact with the open air except in sanatoria, and for this reason he favored the establishment by the State of a very expensive system of sanatoria for the care of the sick poor. The legislature should be informed that the object of this was not merely to secure better isolation, but that multitudes could have a chance for recovery by methods which could be secured only in that way.

**Co-operation of Laymen Desirable.**—Mr. Edward T. Devine, Secretary of the Charity Organization Society, said that he had been delighted with the discussion this evening, for it seemed to augur well for the great army of the poverty-stricken. He had had the pleasure that very day of calling upon the mayor, as one of a committee to urge a reform in the building-laws, intended to secure more light and air to our tenements. A formal protest had been recently received in his office from the associated charities of Los Angeles, Cal., against the practice of sending persons on the verge of destitution to that place in the vain hope that they would be cured of their tuberculosis by the climate. We should not expect to throw off the burden in that way upon distant parts of our country. It had been asserted before the legislature that the chief benefit from such legislation would come to the more thickly populated districts—a very unequal distribution. In conclusion, he urged that the medical profession should seek the co-operation of their lay friends in educating the public on this topic.

**Tuberculosis and Poverty.**—Mr. Lee K. Frankel, manager of the United Hebrew Charities, was the next speaker. He said that during the past fiscal year the United Hebrew Charities of this city had had twenty-three thousand applications for assistance, of which over forty-five hundred had been new this year. Of these forty-five hundred persons twenty-four per cent. had been in the United States less than one year, and most of the applications had been not for relief in money, but for tools to enable the newly arrived immigrants to become self-supporting. On the other hand, the records showed that fifty-eight per cent. of the applicants had been in the country over five years. The causes of illness among this class were in the main the improper sanitary and economical conditions prevailing in this city. He found that three per cent. of the applicants this year had been afflicted with tuberculosis, *i.e.*, one hundred and thirty-five had been suffering from the disease, for the most part in the early stage. Out of the total number of new applicants, in twenty-seven per cent. the sole cause for asking for aid had been illness. They had on their books at present nearly five hundred tuberculosis cases. A great deal had been done by their organization for these unfortunates by the establishment of hospitals and small sanatoria, and in transporting them to the far West; yet all this was but a drop in the bucket.

**State Aid Should be Invoked.**—Mr. Homer Folks, secretary of the State Charities Aid Association, said that in his work he had met with many persons with incipient tuberculosis mingling intimately with those far advanced in the disease. He then spoke of the work that had been done for the insane and epileptic, and argued from this that it was a thoroughly sound policy to attack the tuberculosis problem in a similar way by invoking the aid of the State. Last year they had supported the bill introduced for the establishment of a State sanatorium, and stood ready to give the same support to another similar bill should one be introduced at the coming session of the legislature.

**The Laity Ready and Willing to Help.**—Mr. Frank Tucker, general agent of the New York Association for Improving the Condition of the Poor, spoke of the way in which they were confronted in their work with the ravages of consumption. Last year they had been asked to relieve three hundred and twenty-five families in which the cause of the destitution had been consumption. This disease alone was responsible for a heavy drain upon the charitable resources of a community. It was evident that something must be done, and he was sure that the laity were willing to support any feasible measure for ridding the community of this vast evil.

**A State Isolation Hospital the First Requisite.**—Dr. Daniel Lewis, president of the State board of health, said that all present seemed agreed upon the necessity for having a State sanatorium, but the plan and scope suggested to the legislature last winter seemed to him ill-advised. Hasty legislation was far worse than none at all. His own opinion was that the State needed, first, an isolation hospital for tuberculosis cases, for if such an institution was available there would be comparatively few incipient cases. This should be considered before settling upon a plan which might not prove suitable here, although it had proved so in Massachusetts. He had been asked by the reader of the paper if the State board of health approved of the plan proposed last winter. The proposition had been to have a commission appointed by the governor to locate the site, draw up approved plans, establish a hospital, select and appoint physicians, make rules and regulations for the conduct of the physicians, the care of the patients, and for the general management of a great State medical institution; and yet there was no provision made for a single medical man on the commission. He believed that the State board of health should have a voice in the management of such an institution just as much as the State commission in lunacy should have a voice in the management of the hospitals for the insane.

Dr. Pryor here explained that the bill last winter had been amended to provide for the appointment of not less than two physicians, and the selection of the site was to be left to the approval of the State board of health.

**The Health Board Hospital Plan.**—Dr. F. H. Dillingham said that the board of health of New York City had been working along the lines that had been laid down and approved by the speakers this evening. Since January 1, 1898, up to the present time this board had sent three hundred and thirty-two patients to the Seton Hospital. Of this number one hundred and forty-five had been discharged at their own request. Application having been made to the board of health, the sputum was examined and the diagnosis made by the health department physicians, and then the financial condition of the applicants was inquired into by the Charity Organization Society before their names were placed on the list. There had been at times as many as one hundred on the waiting list because the funds at the disposal of the department had not allowed of sufficient accommodations being provided. The results seemed to justify fully the system adopted, and even its extension. The speaker also stated that the sanitary code had been recently amended so that no cows could be brought into the city of New York without a certificate showing that the tuberculin test had been recently applied to them and had proved negative.

**The Influence of Sanatoria.**—Dr. S. A. Knopf insisted that there must be one or more reception hospitals in the city from which the advanced cases should be selected and separated, and transported to a place by themselves. The incipient cases should be treated in proper sanatoria. A point which should not be overlooked was that sanatoria for consumptives reduced the mortality in their immediate neighborhood, thus effectually removing any reason for opposing their establishment in any community. Much had been said about the odious discipline of sanatoria, but, after all, this was nothing more than insisting that the patients should not persistently and wantonly violate rules established for the general good of all.

**The Subject in a Nutshell.**—Dr. C. E. Nammack summed up the subject as follows: (1) Consumption is a curable disease; (2) our best hope of cure is by increasing the resistance of the individual affected rather than by endeavoring to destroy the tubercle bacilli; (3) good air and food will increase this resistance; (4) the State has or should have an abundance of good air and good food to extend to its poor who are unable to purchase or obtain these commodities.

**Combine the Farm Colony with the State Sanatorium.**—Dr. Wickes Washburn asserted that the statistics of New York County showed a marked diminution in the death rate from tuberculosis, whatever the State at large might show. Prior to 1886 there had been a steady increase, but since that year the rate had steadily diminished, until in 1898 it had been only four thousand eight hundred and forty-three as against five thousand four hundred and seventy-seven in 1886, and this, too, despite the increase in population. This decrease in the number of deaths he attributed largely to the law passed in 1885 giving better light and air to the dwellers in the tenements. He agreed with Dr. Daniel Lewis that, logically, by building a sanatorium for incipient cases first we were beginning at the wrong end. When the sanatorium did come he hoped it would be in connection with the farm colony plan. This would do away with the objection made by many patients to leaving their families and losing the salaries which supported these families. We would in this way reach what Dr. Henry P. Loomis called the "pre-incipient cases," the weaklings in the consumptive's family being included in the benefits to be derived from the farm colony, thus preventing them from contracting the disease.

**Let Us be Good Followers.**—Dr. Meyer, in closing, said that the discussion had been a most interesting and important one, but he hoped it would not end in mere talk. In opposition to what had been said by the president of the State board of health he would assert that, in his opinion, the medical profession had constantly erred on the side of going too slow in this matter; we were at the present time far behind countries supposed to be under an effete government.

**Proposed Action.**—Dr. Nammack then offered the following preamble and resolution:

*Whereas*, The prevalence of pulmonary tuberculosis, especially among the poor, has been, and continues to be, the cause of more deaths among the citizens of this State than any other disease; and

*Whereas*, the great value of treating incipient cases in sanatoria under proper conditions has been demonstrated both abroad and at home; and

*Whereas*, The inadequacy of private endeavor, however well directed, in dealing with this enormous problem is admitted by all who have made a study of this question; therefore, be it

*Resolved*, That the Medical Section of the New York Academy of Medicine recommend the establishment of State sanatoria for tuberculosis; and furthermore, that three members of this section be appointed to confer with the Council with a view to having this subject referred to the Academy for action. Carried.

**Vote of Thanks.**—On motion of Dr. Knopf a vote of thanks was accorded the guests of the evening and to the chairman of the section for the interest taken by them in arranging for this meeting.

---

## SECTION ON SURGERY.

*Stated Meeting, October 9, 1899.*

Charles N. Dowd, M.D., Chairman.

**Two Cases of Resection of Stomach for Carcinoma.**—Dr. B. Farquhar Curtis presented two cases of resection of the stomach for supposed benign tumor, which proved to be carcinoma. As these cases had been seen in the very early state, he believed the prognosis to be quite good. The first case was that of a man of twenty-eight years, who had enjoyed exceedingly good health previously. The stomach symptoms had dated from five years ago. There were distress and eructations of gas after eating, which gave relief. About three years ago the vomiting had begun, and had persisted since that time. Mucus had been present in the vomitus, but no blood or coffee-grounds material. For eighteen months he had been using the stomach tube for washing out the stomach. He had lost fifty pounds. On admission to St. Luke's Hospital in August he was found to be in good general condition. The stomach descended lower than normal, and its walls seemed to be thickened. A hard tumor, not tender or painful, was detected on examination, and was connected with the stomach. The total acidity of the gastric juice had been much reduced. The urine contained no albumin. On August 5th an operation had been undertaken for a supposed benign fibrous thickening of the pylorus. The region of the pylorus had been explored through a vertical incision. A few slightly enlarged glands had been found close to the tumor, and these had been enucleated. The peritoneal and vascular attachments of the pylorus had been ligated and divided. The tumor was slowly excised, a portion being cut at a time, and the wound in the stomach sewed up before going further, thus opening up only a small part of the stomach at a time. The method of resection was that known as Kocher's, except for the use of the Murphy button to unite the stomach with the duodenum. The patient's pulse did not reach above 126, and the temperature had remained normal after the third day. Rectal feeding

had been begun at once. In forty-eight hours food had been given by the mouth in drachm doses. The wound had healed primarily, and the button had been discharged ten days after operation. The patient had gained twenty-eight pounds in the thirty days following the operation.

The second case was that of a German woman, twenty-eight years of age, who had been admitted to the hospital on July 31st. Her health had been good previously. After the birth of her child, fifteen months before admission, she had experienced some nausea and pain about the stomach. She had noticed about the same time a little blood in the vomited matter. Her principal complaint was a pain in the lumbar region, occasionally radiating to the shoulder. She appeared anæmic. A hard tumor, about half the size of the fist, could be felt just above the umbilicus. The stomach appeared to descend to the umbilicus. No nodules could be felt. There was sufficient pain in the neighborhood of the tumor to demand the use of morphine at night. The absence of stomach symptoms had made the diagnosis quite difficult. The leucocytosis present implied an inflammatory condition. As there had been some signs pointing toward syphilis a diagnosis had been made of a gumma attached to the rectus muscle, and breaking down. On August 12th, under ether anæsthesia, an exploratory vertical incision over the rectus had been made. The peritoneum under this muscle had been found thickened, as had also been the anterior wall of the stomach, the latter being adherent at this point. A small, hard, apparently carcinomatous gland had been found above an ulcer on the lesser curvature of the stomach. There were about two inches of healthy stomach between the pylorus and the neoplasm. By Kocher's method the growth had been removed, together with what would represent about two-thirds of a stomach of normal size. An ulcer nearly three inches in diameter was found in the mass removed. The operation was long and tedious, and the patient experienced considerable shock. Immediately after the operation the temperature had been 105.2° F. The speaker said that he had been studying these elevations of temperature after operations, and had come to the conclusion that, in most instances, they were due to shock. This seemed to have been the explanation in this case, because seven hours later the temperature had fallen to 101.4° and the pulse was 120. She had fed per rectum for ten days. She had been given water on the fourth day, and milk on the sixth day. She had felt no hunger until two weeks after the operation. On the thirty-second day after operation she had weighed eighty-seven pounds, while at present she weighed one hundred and five pounds. The examination of the first specimen showed that the walls measured three-fourths of an inch in thickness, and that there was an absence of ulceration. The original cause of the growth was in doubt. Unfortunately the glands had not been examined by the pathologist. The growth and the glands in the second case had been pronounced by the pathologist to be undoubtedly carcinomatous. Apparently a benign ulcer had been the starting-point.

Dr. W. B. Coley remarked that the Murphy button was very useful in this class of cases.

Dr. Charles N. D. Jones asked if Dr. Curtis was of the opinion that in the second case the inflammatory exudate formed after the ulcer of the stomach had been changed into carcinomatous tissue.

Dr. Curtis said that in the first case an examination, made in the medical wards, had shown at one time a complete absence of hydrochloric acid, and the presence of lactic acid in the stomach. As hydrochloric acid was absent in other conditions that might be confounded with carcinoma, this result of chemical investigation did not give much diagnostic aid. The presence of lactic acid pointed somewhat more strongly to carcinoma. Carcinoma was usually the result of some chronic inflammation or irritation, and hence it seemed to him justifiable to resort to exploratory laparotomy, or even to a gastro-enterostomy in inveterate cases of so-called dyspepsia. The operations, in the cases reported, had lasted from one hour to one hour and a half. He thought it had been shown that Kocher's method gave the best results—far better than a lateral gastro-enterostomy.

**Volvulus in an Adult.**—Dr. John F. Erdmann presented a man, forty-two years of age, upon whom he had successfully operated for volvulus. On July 24th this man had complained of slight pain in the abdomen. This had increased for four days, at which time the speaker had seen him in consultation. There had been no vomiting and no movement of the bowel for four days. When first seen the pulse had been 140 and rather feeble; the abdomen had been tympanitic and quite painful. No tumefaction could be felt. There had been considerable tenesmus and one mucous stool containing blood. The man had been given strong purgatives of all kinds. On July 28th he had been admitted to the Gouverneur Hospital with a pulse of 148 and a temperature of 102.5° F. An incision had been made through the right rectus muscle up to the umbilicus. This had exposed an enormously distended coil of intestine. It had been found that the dilated and thickened sigmoid extended up to the xiphoid cartilage. The twist was situated opposite the third lumbar vertebra. It consisted of a full twist of 180° from left to right. He had carefully anchored the intestine so as to guard against a recurrence of the volvulus, and the man had made an uneventful recovery, and had had no return of the volvulus. It was his custom to make the abdominal incision through the rectus muscle with the object of interfering as little as possible with the strength of the abdominal wall.

Dr. Curtis, speaking to the question of the best method of conserving the strength of the abdominal wall after such operations, said that he did not believe in the use of a truss after an operation for hernia, because of the peculiar mechanical conditions present. A truss could not prevent the tearing open of the ring of the canal through which a hernia must make its way, although it would prevent the descent of the hernia after it had once begun. In the case of an abdominal incision the condition was very different. To prevent the distention of the belly by the downward pressure of the diaphragm after laparotomy he was sure the abdominal belt was useful, and certainly it increased the patient's comfort. A proper development of the muscles, however, was very important, particularly in hernia cases. After the first year the use of the bicyle in moderation was advisable.

Dr. Coley also spoke in favor of the use of the belt, particularly in cases having a long scar. With an incision of moderate length, made through the rectus muscle, and healing by first intention, a belt might not be necessary, but, as a rule, it was useful.

**Fracture of Patella—Mediate Suture.**—Dr. Percy R. Bolton presented a man, thirty-seven years of age, who had entered Bellevue Hospital three years ago, after having sustained a fracture of the right patella. After the joint had been immobilized for three days, an incision had been made into the point and the fluid and blood evacuated. He had then sutured the aponeuroses of the vasti together, practically approximating the fragments. He had next sutured the periosteum and immobilized the limb in extension. The sutures had been removed after about one week and the limb kept in plaster of Paris for five weeks. Passive motion had then been carried on until flexion had

exceeded 90°. There had been complete restoration of function, and it was now impossible to detect the site of the fracture.

Dr. Curtis said that last fall he had operated upon a bad case of fracture of the patella. He had sutured the aponeurosis with catgut. The man had left the hospital wearing a posterior splint of plaster for support. A few weeks later, while standing in a car, he had been jolted and the patella was again fractured. This time the patella had been wired, and the man had left the hospital a second time with a useful limb. Last spring he had returned with another fracture of the patella. The speaker's colleague, Dr. Gibson, had operated and found the wire sutures in place, but they had torn through the bone. The man had since worn a posterior support.

**Tuberculous Inguinal and Pelvic Lymph Nodes Following Wounds of the Foot.**—Dr. Charles N. Dowd presented two children who had had tuberculous inflammation of the inguinal glands following infected wounds of the foot. The boy had come to St. Mary's Hospital with an enlarged gland which, on incision, had appeared to be a simple infection. The pathologist had, however, reported the gland to be tuberculous, and shortly afterward the pelvic lymph nodes had become infected. He had then followed the glands up into the pelvis. The child was now in much better general condition. Another boy presenting almost the same condition was also exhibited. Last April he had been admitted to the hospital with an abscess above the knee and enlarged lymph nodes in the groin. There had also been a sluggish sore on the foot. The glands had been removed in this case above Poupart's ligament. Dr. Dowd said that he had met with a great many such cases at the hospital, showing that they were not so rare as one might suppose from the few cases reported. In one of the cases the appearance of the wound of the foot had led him to believe that tubercle bacilli had been introduced into this wound, and it was extremely probably that the same mode of infection had existed in the other case.

Dr. Dowd also presented a girl who had had persistent trouble with the cervical lymph nodes. She had been first seen in December, 1896. The lymph nodes had been removed from both sides of the neck and from both axillæ, and at last the child seemed to be in good condition. She was the worst case of the kind that he had ever encountered, yet he thought her chance for an absolute recovery was very good indeed. He insisted that it was worth while to follow these cases persistently and remove the nodes.

Dr. Jones asked Dr. Dowd if he did not think the keloid in the foot was the result of tuberculous infection.

Dr. Dowd replied in the negative, adding that the history of the case was opposed to such a view.

**Congenital Hernia of the Umbilical Cord.**—Dr. W. B. Coley reported two cases of this very rare condition (to appear in a future issue).

**Appendix in Hernial Sac Containing Three Gun-shot.**—Dr. Carl E. Pfister reported the following case: A. C——, twenty-two years of age, had come to him two weeks ago with a small right inguinal hernia. He had stated that a truss only increased his pain, and that he desired to be operated upon. On September 28th a Bassini operation had been done on him, and it had then been discovered that the twisted vermiform appendix was in the sac and adherent to its wall. The appendix having appeared to be pathological, it had been removed, the stump inverted, and the operation finished by transplanting the cord and closing the wound after the usual manner for a Bassini operation. The appendix had not only contained considerable fecal matter but three No. 8 gun-shot. On inquiry the patient had stated that he had often played slingshot, and while thus engaged was accustomed to hold twenty or thirty shot in his mouth, and that occasionally he had swallowed a few of the shot. The speaker went on to say that in the Hospital for Ruptured and Crippled the presence of the appendix in the hernial sac had been noted fifteen times in children—in one instance on the left side—but in all of these cases the appendix itself had been normal. Of one hundred and two adults on whom he had operated he had met with the appendix in the sac in only three, and only in the case reported had it been necessary to remove the appendix.

Dr. Coley said that he had found the appendix much more frequently in the hernial sac than was commonly supposed, but he had not had occasion to remove it more than two or three times. When rather firmly adherent it was wiser to remove it. It was much more common to find the appendix in the hernial sac in children than in adults.

Dr. John B. Walker recalled a case in which a piece of solder had been found in the vermiform appendix.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING OF THE SESSION—INTRODUCTORY LECTURES—BUST OF MORGAGNI PRESENTED TO ST. THOMAS'S HOSPITAL—THE LATE SIR CHARLES ALEX. GORDON, M.D., K.C.B., H.Q.P., ETC.—LEICESTER DEFIANT.

London, October 6, 1899.

The winter session is now in full swing. The old custom of an introductory lecture is being given the go-by at an increasing number of the schools, and some of our senior friends regard this with much regret. Some whose alma mater has joined the new plan drop into another institution to revive memories of the opening day. It is well perhaps that some of our schools have not gone over to the party of conversazione and amusement.

At University College, Dr. Blacker, in view of the magnificent new hospital now building, and in which the students would carry on part of their work, dwelt on the past history of the hospital and gave some interesting biographical sketches of past members of the staff. But, he added, it is not enough to rely on the traditions of the past; they must build up traditions of their own. He told the students they should add to their professional knowledge improved general education and knowledge of the world, and if a man reads too much he may have little time left for thought. Robert Hall said of a learned but rather dull personage: "He had so many books on his head that they pressed on his brain." "So," added Dr. Blacker, "he is a poor doctor whose sole attainment is a knowledge of physic."

At St. George's Hospital, Dr. Howship Dickenson again appeared and descanted on "Medicine, Old and New." In modern treatment the antipyretics which have come into fashion he pronounced often injurious, if sometimes useful. If nature raises the temperature, he said, art is called in to lower it, as if the danger lay in the temperature rather than in the condition which raised it. He regarded high temperature not so much as a danger as a sign of danger. Antipyretic drugs, too, are depressing, and it may be that some who might have survived their diseases have succumbed to them and the treatment combined. He had known recovery to occur after a temperature of 111° F. with-

out any special means of reducing it being employed. He then passed on to consider the substitution of scientific for empirical methods, which has resulted in great progress and enabled us to compass achievements, mostly in prevention, but to some extent in cure, which we ourselves must wonder at and which our forefathers would have thought impossible.

At St. Mary's Hospital, Dr. H. G. Plimmer divided the study of medicine into that part which relates to practical usefulness and that which concerns scientific investigation. Each division might attract individuals and each be noble. Students are often told theirs is the noblest of all pursuits, but that, said Dr. Plimmer, is only as you make it so. He defended experiment on animals, remarking that man had surely as much right to use them for science as for food or war. The partisans of the crusade against science had no objection to experiments on man, as in the tremendous experiment now being carried out on thousands of English children.

At Charing Cross Hospital, Dr. M. Bruce took a hopeful view of "The Present Outlook of Medicine" on account of the scientific method pursued in every department. He pointed out how different are the work and responsibility of the student and practitioner to-day compared with the time of their predecessors, especially in regard to sanitation. He would have hygiene inculcated from an early period so that children might grow up imbued with the spirit of cleanliness. He advised students to open their minds to the elevating and refining influence of general culture as well as to the accumulations of professional knowledge.

At the School for Women, Mrs. Garrett-Anderson again came forward to encourage the students. She pointed to the new buildings now in course of erection, and said that now the right of women to practise medicine is generally acknowledged and they are doing good work in all parts of the world.

Professor Sims Woodhead gave an address at the Royal Veterinary College, in which he remarked on the enormous rise in status of the veterinary surgeon since the standard of preliminary education had been raised. He also pointed out the necessity of the government having a large skilled staff for studying the diseases of cattle.

Mr. Murray addressed some excellent advice to the students of the Middlesex Hospital, especially urging them to make their own careful observations, think for themselves, and rely on themselves.

The other schools discarded the time-honored lecture and opened with prize awards or distributions and other functions—the majority with a dinner of old students, to which new ones were welcome. Even where lectures were given dinners were common enough afterward, and the speeches were sometimes superior to the run of such occasions.

A very notable celebration took place at St. Thomas' Hospital. This was the presentation of a fine marble bust of Morgagni by the Italian ambassador on behalf of an Italian committee, which includes some of the most distinguished professors and doctors in the peninsula. The ambassador performed his task with the utmost grace, and passed some pretty compliments on the men who have worked or are working at St. Thomas'. Then Dr. Payne gave an account of Morgagni's life and work, after which Professor Allbutt addressed the students. He advised those who could do so to learn their science at a university and obtain their clinical instruction at such a great hospital as St. Thomas'. It was a great day for St. Thomas', and was of course wound up with a dinner and more speechifying in the evening.

Surgeon-General Sir Charles Alex. Gordon, K.C.B., M.D., Honorary Physician to the Queen, died on Saturday, September 30th, aged seventy-eight years. He entered the army as assistant surgeon at the age of twenty years, and served in all parts of the world until he retired in 1880 and was awarded a pension for distinguished and meritorious service. How richly he had deserved this may be seen in but a few of the many services he performed. In the Gwalior campaign, on the West Coast of Africa, through the Indian mutiny, in China, and elsewhere he was actively engaged. For the Indian mutiny he received a C.B., with medal and clasp for Lucknow. During the Franco-German war he was sent by the war office as medical commissioner to the French army. He was shut up in Paris throughout the horrors of the siege and devoted himself to the care of the wounded when weak and suffering through the famine. When the Communists got the upper hand, he nearly lost his life from their rash error. A number of them mistook him for a German spy, seized him, bound him, and were about to shoot him, when one of their superiors came by who knew him and told them who he was. This veteran soldier-surgeon was so modest that he could not easily be made to speak of this or his many other hairbreadth escapes. Once I asked him suddenly how he felt when the firing party were levelling their rifles, and he merely said, "Well, I thought of my wife and children." The French government afterward made him an officer of the Legion of Honor, and he was elected honorary member of various French medical societies. On returning to England he published a volume entitled "Lessons on Hygiene and Surgery from the Franco-Prussian War." He had previously written an important work on "Army Hygiene," a volume on "China from a Medical Point of View," and others relating to the work of army surgeons. Later on he was again sent to India as principal medical officer at Madras and accompanied the governor-general to Burmah. He wrote a volume on this trip also. It will be seen he wrote a good deal, having the pen of a ready writer and being always desirous to share his knowledge where it might be useful. Besides separate works he contributed largely to the journals. His services in so many climates were thus utilized, and his experience and information were extensive. He was a good naturalist in the old broad sense, very fond of birds and animals, and very tender-hearted withal, to which no doubt was due his great dislike to the muzzling of dogs. Sir Charles received promotion in the Order of the Bath on the occasion of the Queen's Jubilee, and also received the Jubilee Medal.

On Monday the Leicester Guardians decided by twenty-eight votes to nineteen to defy the High Court by refusing to obey the mandamus requiring them to appoint a vaccination officer.

The War Office advertises for civilian surgeons to fill vacancies at home caused by the departure of many officers of the Royal Army Medical Corps for South Africa.

## YELLOW FEVER AND THE PROBLEM OF THE TROPICS.

To the Editor of the Medical Record

Sir: In the Medical Record of September 23d I read a leading article, "Yellow Fever in Cuba." It dwells upon the actual favorable condition of Havana, and a hope is expressed that some time that scourge may be stamped out. No doubt a great deal can be done by intelligent and careful sanitation to restrict the extent of yellow fever, and no doubt again that the Spaniards never did much or let us say anything in that respect. They and the Cubans and the people of this country, and all the Southern races, are much too unclean by nature and much too indolent and too superstitious, and will expect more from a high mass,

a procession, or an offering made to the "Holy Virgin," than from all the disinfectants put together.

The people of Vera Cruz, for instance, offer resistance to the carrying through of sanitary measures; so the city board refused to pay for disinfection, even when the government had given strict orders to this effect. Bear in mind that for those acclimated and living in an unsanitary port the yellow fever is a kind of premium to keep competition away. I suppose what we may say of Vera Cruz, with very little difference applies to all the ports where yellow fever breeds.

The efforts made by your people to improve the condition of Havana, etc., are certainly worthy of every praise, and will no doubt lead to a considerable limitation of yellow fever. But will you ever be able to eradicate it altogether? I believe not. The precise reasons why some years the fever is mild and other years furious are not yet known. And now let me relate a fact with regard to Vera Cruz.

That place was a fortified town, and had until some twenty years ago no clear, fresh water; but the people in the majority during the rainy season collected water in tanks, which, when the rains began early, were not emptied for two or three years. But occasionally these cisterns—not always underground, but covered—were emptied and scrubbed, or at least lime and common salt were added to the water that remained over the year. That water was not at all unhealthy nor unpleasant to drink.

Then an aqueduct was made to bring sufficient good water from the Jamapa River, and people said: "Now that we have plenty of good and healthy water, we shall get rid of yellow fever." In fact, there came a year with very few cases, and then a year when during the whole fever season there were but two cases of yellow fever in the city of Vera Cruz, one coming from the country and one from Vera Cruz itself, and in the whole state of Vera Cruz there occurred only four or five cases. The enthusiasts were triumphing; the yellow fever, it was thought, was soon to be a matter of history. But it took a sudden start again.

Then people said: "We must have better ventilation; let us pull down the walls of the town; then the wind will sweep freely through our streets, and the yellow fever will be expelled." The walls were pulled down, and the fever did not stop. Actually, on account of the harbor works, the town of Vera Cruz is in a pitiable sanitary condition, and we may say, without being taxed with exaggeration, that whatever might be done to improve that condition is left undone.

Let your people continue their praiseworthy work in Havana, Santiago de Cuba, etc., and not be discouraged if after a favorable year there should come an unfavorable one.

In your issue of September 30th is an article, "The Problem of the Tropics." On that I have likewise something to say. What will you understand by "tropics"? In the tropics a man can live from the seashore up to an elevation of five thousand or six thousand feet. Elevation makes a mighty difference. A white man may become acclimated perfectly well and live long and happy at any place elevated from three thousand feet up. Then what is the white man's life to be? If he lives in an office, a factory, works at a handicraft, etc., or if he is a capitalist and takes good care of himself, he will be all right. But if he undertakes to work outdoors and in the blazing sunshine, he cannot compete with the Indian in salary, and he will soon find out that he has made a miscalculation. And speaking of colonists, I absolutely indorse Mr. Benjamin Kidd's opinion, that the attempt to acclimatize the white man in the tropics (*i.e.*, in places under three thousand feet elevation) is a blunder of the first magnitude. I am not sure that Mr. Kidd expresses the opinion only of the minority—quite on the contrary; and Drs. Manson, Sambon, and Cantlie would soon be found to represent the minority, if only their "certain conditions" were more fully explained. Yes, a man who is able to take every possible care of himself, not to expose himself to the sunshine, nor to the rains or the cold morning air, may live anywhere, but such cases are exceptions to the rule. Never mind what *The British Quarterly Review* says; I say I am not a pessimist because my opinion differs from that of *The British Quarterly Review;* what I say is my experience and conviction. Many tropical countries will never be in good sanitary conditions, and the malaria mosquito will never be exterminated.

Another important question is the food the white man should take when he lives in the tropics and the clothing he ought to wear. We will presume, first of all, that the said white man has the necessary means to get convenient food and dress, which a colonist will not have, certainly not at the beginning. No white man can live on what the indigenous to the tropics can, either with regard to quantity or to quality. My rule is: Let him live as well as he can, and if he be accustomed to spirituous drinks, I recommend him, not total abstinence—far from it—but great moderation. The enervating and weakening climate of hot countries clamors for some stimulant and supports it very well.

It may be that less meat is required in warm countries, but that cannot be settled in a few words. What is much and what is little? These are cases of individual habits and appreciation.

If I am not mistaken there is a prize offered in the United States for an ideal diet list for men, principally soldiers, in hot countries. We will see what comes of it.

And with regard to clothing, we have to remember that in the tropics the middle of the day is generally quite warm, the evenings are cool, and the early mornings often chilly. The dressing must be such as to prevent colds and drenching as far as can be.

DR. SEMELEDER.

CORDOBA, STATE OF VERA CRUZ, October 8, 1899.

## THE UNFAVORABLE WINTER CONDITIONS OF EGYPT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In search of a suitable winter climate for an invalid suffering from chronic bronchitis, and acting upon the advice of friends and physicians, we set sail, via Gibraltar, the 5th of November of last year, arriving at Cairo, after a short stop at Naples, the 29th of that month. We had fair weather until December 13th, then a short rain-storm, and after the 15th colder days and nights. From that time until about the middle of February the Cairo winter weather prevailed—sunshine most of the time, with chilling north winds, giving birth to disease and making the air of the nights most dangerous for those who were suffering from throat and chest afflictions.

If my two months' experience in helping another through an acute case of pneumonia at Cairo proved anything, it is that the winter climate of that city is the most deceptive and as dangerous as I had ever encountered for people suffering from affections of the throat, chest, or lungs. Besides the defects of climate there are other reasons why delicate invalids should avoid Cairo. It is in many respects most insalubrious, having neither drainage nor a soil capable of absorbing water. After a rainfall, the water remains in the gutters until dipped into carts and sent away. This is not an effective way of disposing of mud and

slush, as a considerable quantity always remains in the gutters after the carting has ceased.

The filth and the smells of the old city—the native quarters—are particularly offensive and abundant, so much so that very few Europeans venture to live there. The narrow passages and streets by which they are intersected are usually reeking with the accumulations of vegetable and other repulsive disease-producing substances too offensive for description; and the sight of strangers holding handkerchiefs over their noses as they pass through them is not an infrequent one. To describe correctly the Arab part of Cairo life, it may be written that the native Arabs enjoy filth and foul air, and are unclean in their habits; and wherever they are found living together, in large or small communities, we are sure to find unspeakably filthy conditions, such as must be avoided by those who care to preserve their health.

Among the dozen or more large hotels in Cairo, there is not one properly prepared to give comfortable accommodations to guests during the winter season—and I doubt if one of them has a comfortably warmed sitting-room, where delicate people can pass the evening hours without taking cold. They are, purposely, not arranged for heating, or, in several other important respects, for making their patrons safely comfortable during the cold season. They are managed like summer hotels in a place where the nights have a peculiarly dangerous chill, which, in my varied experience with a great variety of winter climates covering a period of thirty-four years, I had never encountered elsewhere. The hotel, the largest and most popular in Cairo, where it was my misfortune to have been caught with an acute case of pneumonia on my hands, I regard as being a very dangerous place for delicate people. A considerable part of the office floor, made up of various passages, all sucking in the cold air from outside, has been converted into a foyer, where, in my belief, more colds are contracted, and the foundations laid for a greater number of serious diseases, than in any other like space I have ever known. It is the abode of draughts which intersect each other from all available directions and throw down their victims by the score, and I doubt if it would be possible for one suffering with a throat, chest, or lung complaint to escape from the unfortunate consequences which would flow from spending their evenings in a place suitable only for those who are strong and watchful.

The best-known doctors of the place are of the Sangrado sort. It was my misfortune to encounter two of them; one had lived in Cairo twenty-nine years, and the other twenty-five. One was in daily consultation, so he said, at two guineas a visit during the first week, and the other had charge of the case, as attending physician, from the 23d of December to the 19th of January. During his twenty-seven days in charge, he wrote upward of forty prescriptions, which enriched the drug-shop keeper, and made his unfortunate victim grow steadily worse. Fortunately, however, he was discharged just in time to save her life, as undoubtedly another week of his in-the-dark dosings would have ended the existence of his patient. In his place was employed an up-to-date young Englishman, who was just out from England for change of climate. At once he abandoned all doses, fed liberally, and got his patient out of bed and into the open air as soon as she could walk. In one month, under his intelligent treatment, she had quite recovered from a dangerous disease, which had been supplemented by the most unintelligible and cruel treatment of the cavalry-horse sort I had ever witnessed.

These particulars in relation to medical treatment are given for the purpose of showing what strangers may encounter who go to Egypt for its supposed favorable winter conditions. Since the English occupation, particularly, Egypt has been steadily "boomed" for the superiority, over all others, of its winter climate, and good care has been taken to prevent a showing of the other side. There seems to be a perfect understanding between the hotel-keepers, couriers, conductors of excursion parties, Nile transportation companies, newspaper men, and possibly doctors, that the facts in relation to illness and death should not get out. During the three months I was compelled to remain in Cairo no case of death among strangers was mentioned, so far as I know, in either of its newspapers, and the correspondents of foreign journals were equally discreet in not communicating disquieting facts. And yet deaths among that class were of frequent occurrence, both at the hotels and hospitals.

Among the diseases most in vogue typhoid is always in the lead, followed by a series of dangerous maladies resulting from sudden colds and chills, usually contracted under prevailing unfavorable conditions which could not be avoided.

This statement, founded upon my own experience, is sustained by many others who went to Egypt expecting to find a safe and pleasant climate suitable for a winter residence for invalids, and especially for those suffering from throat and chest afflictions, and who like myself were disappointed as to climate and other essential conditions. This communication is meant for a warning to those intending to go to Egypt in search of health; and also to cause our physicians who may happen to read it, many of whom now recommend that country above all others for a pleasant and health-giving winter residence, to investigate outside information, not published in the interests of Cairoans, who live almost exclusively upon this extortionate traffic which flows from the ignorant credulity of visiting strangers.

My conclusion is, that perfectly healthy people, able to pay the exceptional cost attending the winter residence in Cairo, may, if they are very careful, go there for that season and get safely through it. But they must make up their minds to put up with many inconveniences, such as cold rooms, poor and non-nutritious food; and to enjoy a scale of prices generally not to be found elsewhere, save possibly in our own extra-favored country.

## THE APPROVAL OF THE INCORPORATION OF CHARITABLE INSTITUTIONS BY THE STATE BOARD OF CHARITIES.

To the Editor of the Medical Record.

Sir: Among the duties imposed by law upon the State board of charities is the following: to "approve or disapprove the organization and incorporation of all institutions of a charitable, eleemosynary, correctional, or reformatory character which are or which shall be subject to the supervision or inspection of the board." This law had its origin in a widespread belief of the people that the charitable institutions of the State are being multiplied far beyond the needs of the dependent classes, and that large numbers exist for the benefit of the officials rather than of the beneficiaries. It was proposed to require of a proper department of the government a careful scrutiny of proposed new charitable organizations in order to correct this abuse of the confidence of the charitable public. In considering the character and scope of its duties the board resolved that one of its members resident in the district where the applicant intended to locate the new charity should institute the following investigations: (*a*) The necessity for the existence of such an institution as proposed to be incorporated, at the time and place and under the circumstances set forth in the

application and certificate; (*b*) the character and standing in the community of the proposed incorporators; (*c*) the financial resources of the proposed institution and its sources of future revenue. It was believed that if this inquiry was made the board would be in a position to determine in a fair and judicial manner the wisdom of establishing the proposed institution and the propriety of selecting a given location.

For upward of five years the board has been performing this duty, and apparently to the satisfaction of the people and of the central government. Many applicants have been denied for one or more of the reasons given above, and it is gratifying to notice the fact that frequently incorporators, who were ignorant of the facts in the case, have expressed their obligations to the board for informing them of the real situation in which they were placed by the promoters of the new charity.

Recently the board disapproved of the incorporation of a proposed new charity for two reasons, viz., (*a*) The class of sick poor which it was designed to benefit was amply provided for in the public hospitals; and (*b*) the institution had no other financial resources than the daily contributions of the people on solicitation through the newspapers. If public policy requires any restrictions whatever upon the multiplication of charitable institutions, the two findings given above would seem to be the proper basis for disapproving of an incorporation, viz., first, that there was no necessity for it, and, second, that it had no adequate means with which to carry on its work. But it appears that *Charities*, "the official organ of the Charity Organization Society of the City of New York," regards the first reason as "a new and, in our opinion, dangerous position." It states that "there are many incurable cancer patients who are not in the public hospitals. If all were to enter them it would make necessary increased expenditures." If all were to enter them, why then a new condition would be created and a necessity might arise for a new private charity. But persons with incurable cancer even among the poorest classes do not as a rule seek hospital care. In general, persons thus afflicted are able to attend to their home duties until the very last stage is reached, and they prefer life in their homes to that in an institution. To meet the wants of these people in their homes the dispensaries have competent physicians to visit them and supply their special necessities.

But, the *Charities* continues, "If a responsible private agency from religious and charitable motives is ready to meet this need it is contrary to precedent and sound public policy to forbid it to do so on the, at best, debatable ground that the public hospital would do it as well or better." The State board bases its approval or disapproval upon the facts and merits of each individual application for incorporation. In the case that gave rise to this criticism it was proven to its satisfaction that (1) the sick poor that the society sought to benefit were amply provided with hospitals in which better care and treatment were afforded than were within the means of the society at the time of the investigation, and (2) the society had not stable financial resources. Whatever value may attach to the principle above set forth by the *Charities* as a rule to govern in the organization of new charities, it is not pertinent to the facts in the present instance. The same is true of the further statement: "The action of the State board goes far beyond this when it prevents the incorporation of an agency which proposes to perform a definite service which is not now adequately performed . . . by either public or private agencies." The State board has never prevented the incorporation of an organization when the conditions, on investigation by one of its members, were such as are stated in the last paragraph above quoted.

The *Charities* concludes as follows: "We trust, however, that the board will not make a practice of refusing to approve incorporation because of such reasons as are set forth in the first part of the present report, which discusses the wisdom of the undertaking and the propriety of selecting a given location." This conclusion is consistent with the general tenor of the criticism, which is in opposition to restraints upon the incorporation of new charities on the ground that these tend "to discourage experiment and the free play of private benevolence." But it is certainly surprising to find the "official organ of the Charity Organization Society of the city of New York" admonishing the State board of charities that in forming its judgment as to its duty in approving or disapproving the certificate of incorporation of a new charity, it must not discuss "the wisdom [the power or faculty of forming the fittest and truest judgment in any matter presented for consideration] of the undertaking and the propriety [fitness; appropriateness] of selecting a given location." To any one familiar with the motives which actuate the promoters of large numbers of modern charities, it is very evident that a certificate of approval or disapproval of an incorporation, based on other considerations than its necessity, the adaptation of its means to the end sought to be accomplished, and the appropriateness of its location to the same end, would have no value in determining its proper status. It is certain that, if the State board of charities should follow the suggestions above made in performing the duties of exercising a proper discretion in certifying to the incorporation of charities, the true intent and purpose of the law would not be fulfilled.

STEPHEN SMITH, M.D.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 21, 1899:

| | Cases | Deaths. |
|---|---|---|
| Tuberculosis | 179 | 134 |
| Typhoid fever | 72 | 22 |
| Scarlet fever | 116 | 6 |
| Smallpox | 3 | • |
| Measles | 140 | 3 |
| Diphtheria | 188 | 29 |
| Laryngeal diphtheria (croup) | 8 | 5 |
| Cerebro-spinal meningitis | 0 | 2 |
| Chicken-pox | 19 | 0 |

**The British Army Medical Service.**—The campaign in the Transvaal will place a great strain upon the medical service of the British army, and in face of the severe strictures made by Dr. Ogston upon the condition of that service it will be interesting to watch the outcome. *The Lancet*, referring to the matter, says: "A very large military force will be required with, of course, a corresponding provision of hospitals and medical service. It is highly probable there will be a good deal of hard fighting before the war is ended, and quite possible that the enemy may be more or less successful in their encounters at the beginning of the campaign, but there cannot be a doubt as to what will be the final end of the struggle, which is really one for maintaining our supremacy in that part of the world. We can only trust that an ample supply of medical officers, hospitals, and hospital stores will be forthcoming. We suspect in this as in all wars the difficulty will be mainly one of transport."

### THE FOURTH HITHERTO UNDESCRIBED DISEASE OF THE OVARY: COLLOID DEGENERATION.

BY MARY A. DIXON JONES, M.D., F.R.M.S.

NEW YORK

THE ovary, on account of its important life changes in the growth and development of the ova, and because of its frequent infection, becomes often the field of most remarkable pathological manifestations. We have seen in the ovarian tissues that peculiar growth, endothelioma; wonderful in its formation, progress, and development, gradually spreading and destroying large portions of the ovary; and in its anatomical characters and clinical symptoms, giving indications of malignancy.

My first specimens in 1885 were labelled "Sarcoma," but a little further investigation clearly proved it to be an endothelioma, formed of endothelia like those which line the peritoneum and the blood-vessels. It was a new disease, giving local pain, and causing distressing constitutional symptoms. At that time, there was no record in medical literature of such a growth, and in studying it I met with new and continued surprises: It soon fills large territories of the ovaries, its peculiar formations extending even to the periphery. As I said in 1889:[2] "Why this growth should have the power of destroying every structure of the ovary, even firm secondary fibrous tissue, or why an ovary should so degenerate, or what is its pathological significance, are still questions for consideration. When we look at this rapidly growing formation, and the great mass of granules, the impression forces itself upon us that it may be malignant. Future investigation may prove it so. Cancer epithelia do not multiply more rapidly, or destroy the tissues more surely, or seem more threatening or monstrous in their appearance and growth."

This growth then, in a most wonderful manner, begins to change into countless millions of blood corpuscles; and amid these myriads of corpuscles, mysteriously begin to appear a multitude of forming blood-vessels. A marvellous presentation! A wonderful revelation, like looking into the secret manipulations of nature.

I soon recognized that this curious formation, this most destructive disease, was found in the ovaries of many sick women, causing in each one pain, feebleness, and emaciation. It proved to be a frequent disease, destroying the life, health, and comfort of many women. There were the seas and lakes of blood, while there was a deathly pallor on the face and a cachexia of the whole system.

But there was yet a more marvellous manifestation. This spreading growth gradually develops in one or both ovaries that most dangerous formation, hæmatoma or blood cyst. It is "Endothelioma changing to angioma and hæmatoma the first hitherto undescribed disease of the ovary."[1]

Next, we have seen large territories of the ovaries transformed into convoluted masses, separated into groups by a scanty amount of dense, fibrous connective tissue, and surrounded by small vestiges of the cortical tissues of the ovary. These hard, gyromatous formations, or convoluted masses, ofttimes filling nearly the whole ovary, destroy every tissue, and give rise to severe nervous and constitutional disturbances. Usually they originate in the structureless membrane, a thin membrane that surrounds each ovum, and at every menstruation one or more is ruptured. When normal, this membrane lies inactive in the ovary, not producing the least disturbance, but when in this little membrane there commences an inflammation, the inflammation spreads, the membrane grows thicker, the inflammatory corpuscles change to extremely dense, fibrous connective tissue, then is deposited a waxy, colloid basis substance, till there is formed a broad, firm, convoluted mass, or great nodular fibromata. This is "the second hitherto undescribed disease of the ovary."[2]

I have also described how all the fine tissues of the ovary may be destroyed by myxomatous degeneration a most remarkable form of degeneration. In its nature, anatomy, and make-up, it resembles a malignant growth, and evidently has a tendency to sarcomatous formation. This is "the third hitherto undescribed disease of the ovary."[3]

All these different forms of degeneration and disease have marked symptoms, well-defined physical characteristics, and they are all accompanied by more or less constitutional disturbance, local pain, and destruction of the general health.

I desire now to describe "the fourth hitherto undescribed disease of the ovary." This is a most curious and wonderful degeneration (see Fig. 1). Who could conceive of such formations? They are like stones thrown amid the fine tissues of the ovary. This is the most remarkable and probably one of the most frequent forms of degeneration of the ovary. It seems especially destructive to those life-like and most important structures, the ova. I have often, by powers of four hundred and of seven hundred, studied the ova thus diseased, and have seen how the various tissues and separate parts were gradually and surely being destroyed by this peculiar degeneration, and how the whole ovary was being infiltrated with colloid corpuscles; some portions being entirely changed to this material, or completely undergoing this degeneration. We see the muscle fibres interlacing, and in the midst colloid masses. Such formations are found in every part of the ovary. Every different structure shows these masses; in many localities much more numerous and more thickly strewn than is here represented. Even in the walls of the cyst, part in acute inflammation, other portions reduced to fibrous connective tissue—indicating that there have been repeated

attacks of inflammation—yet through the whole of the cyst wall, and in every tissue of the ovary, were closely interspersed these colloid bodies. How did they come? What produced them? Why are they there?

Of most momentous importance are the destructive changes which this degeneration produces in the

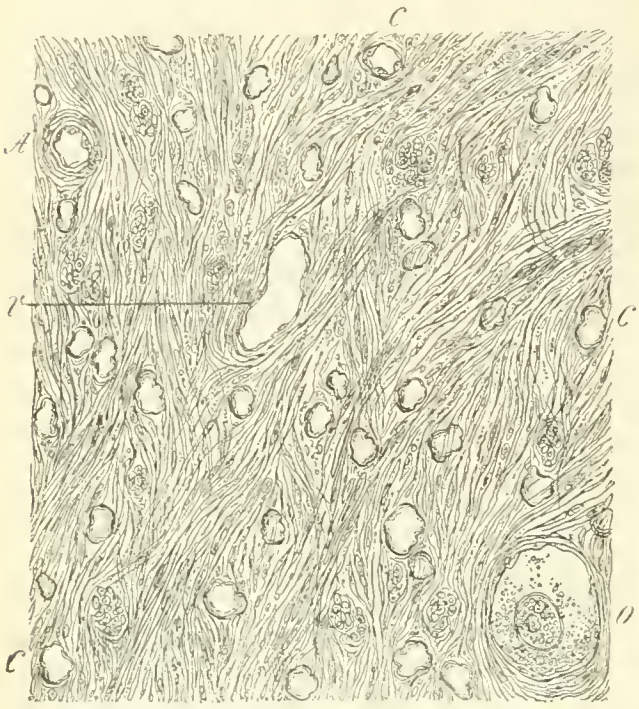

FIG. 1.—Colloid Degeneration of the Ovary. *C, C*, Colloid corpuscles; *O* ovum; *A*, artery; *V*, vein. × 500.

ova. In the cortex of many ovaries, large fields under the microscope, not one ovum is found. In other fields there are small numbers of ova, and they are filled with colloid corpuscles. In many sections are different groups of ova, presenting a most picturesque appearance and showing the different ways in which colloid corpuscles seem to bring destruction to these wonderful life organizations.

To appreciate more fully these changes, let us look for a moment at a normal ovum magnified twelve hundred times,[1] and see the different anatomical elements (Fig. 2). First we see around a clearly defined white line, indicating the basement membrane. Next within this membrane is a layer of epithelia, surrounding the whole ovum. These epithelia are infinite in number, and each one is of beautiful formation. Next, the large or light part is the yolk, then within this yolk is the vesicula germinativa surrounded by its cuticular membrane. The larger or central nucleus is the macula germinativa, a concentration of life material.

Each structure of the ovum has wonderful life power. It is life material, living matter. Probably the fine and high organization of the ova renders them more susceptible to external influences, and more liable to take on morbid conditions. Certainly it is a sad fact that we find, in many ovaries, a diseased condition of the ova.

Fig. 3 represents an ovum in colloid and fatty degeneration. In the surrounding muscular structures of the cortex of the ovary are seen colloid corpuscles. The ovum has advanced in the first stage toward forming a Graafian follicle. The epithelia are short and columnar, and each one is filled with colloid formations, which necessarily destroy their structure, and hinder any further development of the egg. The yolk, the vesicula and macula, the vital parts of the ovum, all seem to be destroyed by large and smaller clusters of colloid corpuscles. There is also fatty degeneration, evidenced by the colorless fat globules. We see that the vital parts, that every normal structure of the ovum, is destroyed. Near this ovum are others equally diseased, presenting an infinite variety as to the distribution of colloid corpuscles within the ova, which colloid corpuscles always carry destruction to the life power of these formations.

Fig. 4 is another illustration of how ova may be destroyed by this degeneration. In neither of these ova do we find any normal structure. In the upper one the remnants of epithelia are recognizable; the yolk, vesicula, and macula are obscured and partially destroyed by colloid masses, and the tendency to a still greater destruction is manifest by the large colloid corpuscle, marked *S*, embedded in the yolk. In the lower ovum, large colloid bodies are massed in the upper portion, and the epithelia, now stratified or columnar, are crowded with small colloid corpuscles, and the granular matter within the epithelia shows a still advancing degeneration. An infinite variety of this degeneration is manifested in the different ova, and each one gives indication of a complete destruction of all capability of any physiological function.

Figs. 1, 3, and 4 represent diseased ova found in the ovaries of the same patient, Mrs. A——, twenty-one years of age. She called at my office, September, 1888, burdened down with sorrow and suffering; sick, feeble, and heartbroken. She declared she had constantly such pain and distress that she could no longer attend to her household duties, but that her greatest sorrow was that she had been married some years and had had no conception. This is a sad side of this disease. In this patient, the uterus was found to be anteflexed, and in extreme retroversion, the ovaries were enlarged and lying below the uterus, and extremely sensitive. The tubes were enlarged, adherent to the ovaries, and contained pus. The patient came repeatedly, with her sad story of sorrow and suffering. She had been under the treatment of various physicians, and any effort of mine to make her comfort-

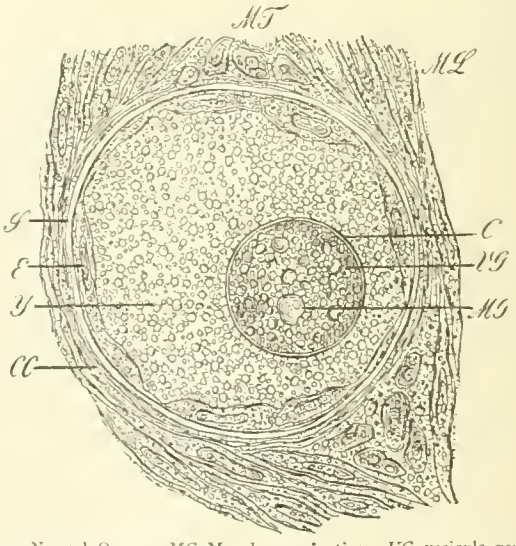

FIG. 2.—Normal Ovum. *MG*, Macula germinativa; *VG*, vesicula germinativa; *C*, cuticula; *V*, yolk; *E*, flat epithelium; *S*, structureless or basement membrane; *CC*, connective-tissue capsule; *ML*, smooth muscle fibres in longitudinal section; *MT*, smooth muscle fibres in transverse section. × 1,200.

able, or restore her to health, would have been equally ineffectual. It was a necessity to remove the dangerously diseased structures. This was done at the Woman's Hospital of Brooklyn, November 10, 1888. The patient made an excellent recovery, and, when last seen, she was in the enjoyment of excellent health. After the diseased organs were removed she had com-

[1] Dalton in his work, "Human Physiology," 1875, p. 685, gives the normal ovum magnified seventy-five diameters

fort, relief, and health. As in other cases, I was determined to know what was the nature of the disease that gave this sick woman so much trouble and distress, and was such a source of suffering.[1] In the ovaries of this patient I find endothelioma, gyroma, pigmented gyroma, oöphoritis, and this colloid degeneration. Pigmented gyroma—that is, the epithelia filled with granules of pigment—may indicate a more dangerous form. All through the cortex of both ovaries are colloid corpuscles. In many sections the muscle tissue is much more crowded with colloid bodies than is represented in this figure. In some sections, placed under the microscope, power of four hundred, there are extended fields and not one ovum, while in similar sections of the ovaries of some women I have counted as many as one hundred and forty, one hundred and sixty-two, and one hundred and ninety-four,[2] but in this case, this peculiar form of degeneration seems to have made complete destruction of many of these fine and beautiful organizations. In other fields, there are small numbers of ova, and they are all filled with colloid bodies. In one section, after many fields where there is not one ovum, comes a field in which there are two ova, both in colloid degeneration, then one ovum with large colloid corpuscles in the yolk, and the vesicula and macula filled with smaller colloid bodies; near by are two ova in one membrane, both in colloid degeneration; then two ova almost destroyed by a crowd of colloid formations, then only a remnant of an ovum, then a shadow where one has been!

Colloid degeneration seems to make peculiar and overwhelming destruction of the ova. By my researches within the last few months I am more and more clearly convinced that ova are certainly and without doubt destroyed by this degeneration, and finally disappear. So many instances are seen in which the ova, reduced to colloid degeneration, are gradually disappearing, sometimes only a dot, or fold

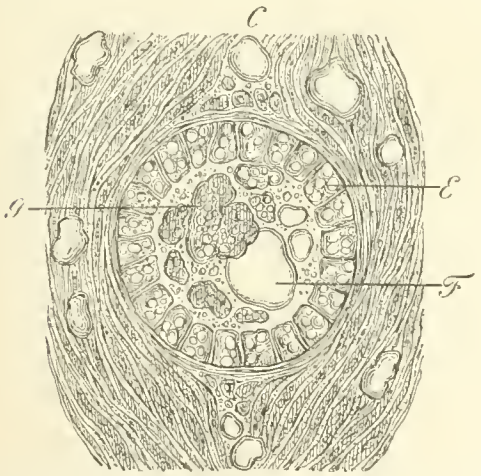

Fig. 3.—Combined Fatty and Colloid Degeneration of the Ovum. *E*, Short columnar epithelium in colloid infiltration; *F*, flat globules; *G* coarsely granular colloid masses; *C*, colloid corpuscles in the muscle layer of the ovary. × 600.

of colloid material is left; then there would be fields with not one ovum, then again fields in which masses of ova are almost destroyed by these colloid bodies; one group of twenty, another group of fifteen, almost gone, and still larger groups in ruins. Thus the ova

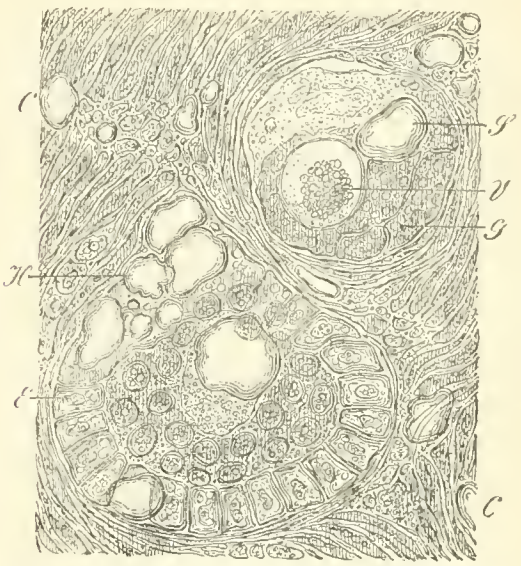

Fig. 4.—Ova in a High Degree of Colloid Degeneration. *S*, Smooth colloid corpuscle; *G*, granular colloid masses; *V*, shrivelled colloid vesicula in a vacuole; *H*, heap of colloid corpuscles, mostly in the epithelia; *E*, short columnar epithelia in an incipient colloid infiltration; *C*, *C*, colloid corpuscles in the muscle tissue of the ovary. × 600.

are changing and disappearing. Of the few left, I do not find in either ovary one normal ovum; all present a most picturesque appearance of ruin and desolation, chiefly from this degeneration.

The walls of several cysts are found in acute inflammation, and in them are scattered many colloid bodies. Near to one cyst whose wall is in most intense inflammation is an endothelioma, and in the endothelia are countless numbers of colloid corpuscles. The fine endothelia are filled with life granules, and amid the life granules are the colloid bodies!

This is the first time, so far as I know, that colloid formations have been recognized in an endothelioma. In some clear spots are seen many endothelia, and in the fine structure of each one, and amid its life granules, are crowded these small colloid formations or granules. It is a wonderful showing!

Cornil and Ranvier in their work[1] give a drawing of cancer. They say (Fig 82, page 104): "Cells infiltrated with colloid matter." This figure presents something of the appearance I have seen in many endothelia, except that the endothelia are probably more marked by being crowded with bright colloid bodies of different sizes. The above-mentioned authors further say: "The cell become loaded with drops of colloid matter, become spherical, vesicular, and finally destroyed." So, according to the opinion of these eminent authors, colloid corpuscles, which we find so frequently destroying the ova, destroy the "cells of carcinoma." The same authors (p. 637) give a representation of "colloid degeneration of the epithelial cells of a uriniferous tubule, in interstitial nephritis"; showing that this degeneration equally destroys the epithelia of the uriniferous tubule.

Delafield and Prudden, in their excellent work,[2] give the same testimony. They say: "The cells of certain carcinomata, especially of the gastro-intestinal canal, may suffer a more or less complete infiltration with a translucent material somewhat resembling gelatin and called colloid, whose nature is not well understood. Sometimes this infiltration is only partial, when the protoplasm of the cells may be more or less encroached upon by the translucent droplets of the colloid mate-

[1] I said in 1890 (New York Medical Journal, May 10, p. 512): "In every instance, in removing diseased structures or any kind of tumor by abdominal section, I have been interested, and determined to know the exact pathological conditions, and thereby find out the cause of suffering and the nature of the disease. So I have pursued sedulously the microscopical study of every case; and these investigations have fully repaid me, not only in the wonderful and beautiful facts they have revealed, but by having enabled me, more intelligently, to help suffering women."

[2] Sappey gives four hundred thousand as the number of ova in a normal ovary. With this gauge, one hundred and ninety-four in one transparent section, we might readily imagine there might be more than four hundred thousand in the ovary of a healthy woman. Nature is always abundant in her supplies. There are more blossoms on the apple tree than ever come to maturity.

[1] "A Manual of Pathological Histology," 1880.

[2] "Pathological Anatomy and Histology," p. 341.

rial; but in other cases, over large areas the cells are partially or entirely destroyed and replaced by the new material, so that the alveoli of the tumor are destroyed by it."

Erichsen[1] gives an account of "colloid material filling the cells of an alveolar cancer." Ashhurst[2] also pictures "colloid material in alveolar or colloid cancer." Why should it be called "colloid cancer"? It is only that in some cases of cancer the epithelia are infiltrated with colloid material. Professor H. C. Warren[3] very truly says: "Colloid cancer should not be considered as a special variety, but rather as a form of degeneration."

Gross[4] gives an illustration of a colloid tumor of the ovary and says: "It is doubtful whether the majority of so-called carcinomas are not really examples of colloid degeneration of the fibrous tissues of the ovaries." But we find colloid degeneration in other tissues of the ovary besides the fibrous.

While in some of the endothelia of the endothelioma there are countless numbers of colloid corpuscles, near by are blood-vessels whose walls are in waxy degeneration, some vessels reduced to a waxy mass, their calibres closed, causing complete endarteritis obliterans. Other vessel are in colloid degeneration; the muscle tissue of the walls is reduced to colloid substance, and the calibres are closed, showing equally complete endarteritis obliterans. In another section of the same ovary is seen an endothelioma, and the connective tissue penetrating it in various directions is in waxy degeneration; and in this waxy connective tissues, and in the endothelioma, are alike scattered colloid bodies; while the neighboring blood-vessels are in extreme waxy degeneration, as also the wall of a cyst is in bright waxy degeneration, and enriched yet more by clear colloid corpuscles, altogether making a picture brilliant, and almost radiant. No one can tell half the beauties and marvels that are repeatedly presented. In every section, new wonders are continually being revealed, and at the same time they are making revelations as to the true pathology of the ovary. In one section of almost a whole of the right ovary, there are first an endotheliomatous growth, then a large gyroma, then another endothelioma; then the whole cortex is bright with colloid formations and wondrously and marvellously diseased ova. In the left ovary of this patient is a group of ova, in the midst of a shower of colloid corpuscles, and these ova are all in waxy degeneration. Again, in a perfect crowd of corpuscles is one ovum in full bright waxy degeneration; another, surrounded by colloid corpuscles, is only a waxy mass. So are seen repeatedly these different and wonderful combinations.

It would be impossible to speak of the pathology of the ovary without considering the morbid changes of the ova. No doubt, one day, the diseases of the ova, their marvellous forms of degeneration and destruction, will be considered one of the most important chapters in the pathology of the ovary. Of equal importance will be the wonderful growths and peculiar formations arising directly or indirectly from diseased conditions of the ova. Changes originating in the ova, or connected therewith, constitute many of the most remarkable pathological developments found in diseased ovaries. The ova are the most vital parts of the ovary. They are not only highly organized, but they are masses of living matter. For them the ovaries really seem to exist. The ovary is only a sack to contain, or a receptacle for, these most important structures; or a laboratory for their marvellous life changes. Apart from the ova, the ovary consists of a few anatomical structures, muscle fibres, connective tissue, blood-vessels, etc. Kölliker, in 1854,[1] gave the following description: "The ovaries are a stroma containing the ova." Dalton's description is: "The ovaries consist of Graafian follicles embedded in a somewhat dense connective tissue, supplied with an abundance of blood-vessels,"[2] and, "In the common fowl the ovary consists of follicles loosely united by connective tissue."[3]

All this shows the exceedingly simple necessities of the ovary. The ova are the important parts. It is diseases of the ova that make the marvellous pathological developments such as gyroma, solid formations, ofttimes filling nearly the whole ovary; or the spreading endothelioma extending to the periphery, and changing all the tissue to a sea of blood; or that peculiar degeneration, myxomatous, which is more apt at any time to develop, because at the bursting of every Graafian follicle there must be repair tissue, which is myxomatous, long since known to constitute the granulating tissue always appearing when a loss of substance is to be filled in. If at the appearing of this repair, or myxomatous tissue, there is an already existing oöphoritis, then from this inflammatory tissue, or protoplasm, a myxomatous degeneration may invade the whole ovary.

Yet another form of degeneration finds its origin in connection with the ova, viz., ovarian cysts. This I have clearly proved by some recent researches, which I will demonstrate at some future time.

All diseases of the ova commence with infection, whether in this infection are microbes or not, or whatever may be the nature of the infection or the names of the microbes; all the same, the disease comes, and goes on spreading general devastation; and somehow the ova seem to be the first affected, often inflamed and diseased even when there is healthy tissue around. In these life formations ofttimes commence the most serious troubles; and we recognize that in them is frequently the beginning of various and remarkable forms of degeneration or change, so often found in diseased ovaries.

Whatever may be the form of the degeneration, it is always preceded by an inflammation, or reduction of the tissues to protoplasm; and from the protoplasm may be developed any kind of new growth or degeneration; growths as above mentioned, endothelioma and gyroma, or more solid "ovarian swellings," as sarcoma, myxosarcoma, "lymphangioma cystomatosum," or carcinoma.

It is a great study, the changes of life material in the human body; and are there any structures that have more vital elements or are of more vital moment than these wonderful organs the ova, from which come every living creature and the whole human race. This wonderful little formation "has the power of reproducing not only ova like itself, but counterparts of every cell in the body." It has such a concentration of life material that in one of the lowest vertebrates "a complete animal may be evolved from as little as one-eighth of an ovum."[4]

Another remarkable instance of colloid degeneration of the ovary was Mrs. F——, twenty-five years of age, married some years, with no birth or abortion. The uterus was retroverted; the ovaries were enlarged, prolapsed, and exceedingly sore and sensitive. In both ovaries are found endothelioma, gyroma, and gyromatous cysts. The walls of many cysts are in intense inflammation; also there is intense oöphoritis in different parts of the ovary; and all through this in-

[4] G. N. Stewart: "Manual of Physiology," Downing College, Cambridge, Eng., 1895, p. 775.

flamed tissue, and through the various degenerated tissues, are thickly scattered colloid bodies. The ova contain similar formations; in many there are colloid masses entirely destroying the vesicula and the macula, and even the epithelia, while near by are ova in waxy degeneration.

Fig. 5 is a most interesting illustration of colloid degeneration found in the ovaries of this patient. The yolk, vesicula, and macula, the essential elements of the ova, are displaced by colloid corpuscles, showing how every separate structure of the ova may be reduced to colloid material. First, the ovum, or portions of it, is changed to protoplasm; then colloid granules appear; they enlarge, have more and more the colloid appearance, and they continue to increase in size till colloid bodies or corpuscles larger or smaller are formed. In the left ovary, the walls of the cyst are waxy, and in this waxy degeneration are colloid bodies. In a gyromatous formation is a little remnant of an ovum, nothing seen but a waxy and a colloid mass. In this ovary also are two ova in one membrane, one in waxy degeneration and the other in colloid; near by another ovum in colloid degeneration, and next to it an ovum in waxy degeneration; then a group of ten ova all destroyed by waxy and colloid degeneration. Such wonderful pictures are again and again presented. In the right ovary many ova are in colloid and waxy degeneration, one partly colloid and partly waxy; another with all the vital parts waxy; then two equally destroyed by colloid degeneration; yet another, and all that remains of it is a waxy mass, and this waxy mass is surrounded by a crowd of colloid corpuscles scattered in fields of intense oöphoritis. Another inflamed cyst wall is filled with colloid formations, and the neighboring vessels are in waxy and colloid degeneration. What is very interesting, the wall of another cyst is reduced to fibrous connective tissue, while near it are fields in waxy degeneration, and in the cyst wall are colloid corpuscles! It is all more wonderful than fairy tales. I write as I see it in the microscope under a power of four hundred (Hartnack lens).

A yet more remarkable example of colloid degeneration was seen in the ovaries of the patient Mrs. I. L. Hunt. This patient called with her mother to see me, February, 1889. She gave her age as twenty-five years, that she had been married ten years, and "ever since her marriage she had constant soreness and distress in the pelvis"; repeating again and again, "I suffer terribly and get worse all the time." On the left side was found an enlargement the size of a cocoanut, and extremely tender. This appeared to be the left ovary, enlarged to a hæmatoma, or blood cyst. Each tube was a sack of pus, and was adherent to its corresponding ovary. The patient entered the Woman's Hospital of Brooklyn. As she lay in her bed she often marked from the outside of her clothing the boundaries of the blood cyst, saying, "There it is, and I want to get clear of it." She begged again and again to have the operation, and was more than disappointed at any delay. It took place in the hospital February 23, 1889. A part of the wall of the blood cyst was so thinned that even with the most gentle handling it ruptured, discharging much dark grumous blood, mixed with pus. The tissues of both ovaries, from subsequent examination, presented evidence of the most profound disease, and complete destruction of all normal structure; as the eminent pathologist, Dr. Charles Heitzmann, deceased, who had opportunities of examining many microscopical slides prepared from sections of both ovaries, said: "There was not in either ovary the least vestige of normal tissue."

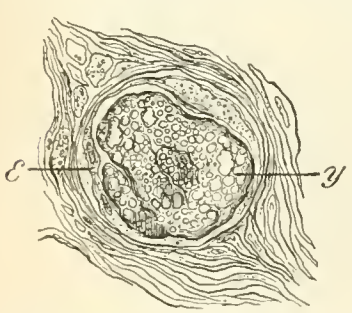

Fig. 5.—High Degree of Colloid Degeneration of the Ovum. *Y*, Yolk and central trace of vesicula germinativa transformed into colloid granules; *E*, epithelium, detached. × 600.

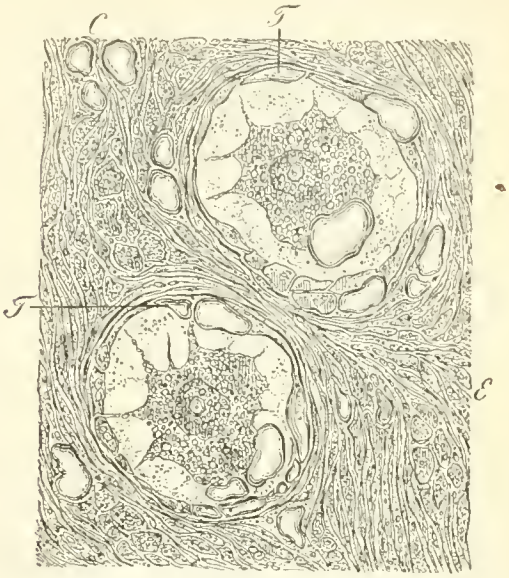

Fig. 6.—Colloid Degeneration of Ova. Colloid corpuscles are seen in the yolk and epithelia of both ova. *T*, *T*, Epithelia in transition to colloid substance; *C*, colloid corpuscles in the stroma of the ovary; *E*, embryonal corpuscles. × 600.

Fig. 6 represents two ova from the ovaries of this patient. The central part, the yolk, and vesicula and macula are transformed into a mass of colloid corpuscles, with not a vestige of the original structure. Large colloid bodies are seen in and around. The epithelia are very much swollen, and in the first stage of forming colloid masses. Many ova have evidently disappeared by one form of degeneration or another. Other ova are as profoundly diseased; not one is capable of any physiological function. It is a sad record. The patient was suffering, and her life was in peril. Without an operation there was no possibility of her life being prolonged.

It is an interesting and remarkable fact, that in the same ovary there may exist at the same time many different forms of degeneration. In the ovaries of the above-mentioned patient, besides the colloid degeneration, there were other grave forms—endothelioma, gyroma, and with these existed an intensely acute oöphoritis; but probably the most serious of all was the large hæmatoma of the left ovary, the walls of which were in extreme danger of rupturing. This of itself, without surgical help, would soon have proved fatal.

Another most interesting example of colloid degeneration: Mrs. M——, a young woman, scarce twenty years of age, had one child; she could have had many more, but disease came. The patient had interstitial pyosalpingitis, and there is found colloid degeneration of the whole ovary. The periphery is in intense inflammation, forming abscesses, while some portions are waxy, yet all filled with colloid corpuscles. Many fields of the cortex have not a single ovum, but are thickly crowded with colloid bodies. In another field appear a number of ova, and every one is almost destroyed by colloid formations, presenting most wonderful and curious pictures. In one field, by a power of four hundred, I counted fifty ova, a heap of ruin. In other places are continuous heaps, all in ruins. Other sections of the ovary show myriads of colloid corpuscles, and the same wonderful destruction of the

ova. Many ova are almost entirely gone by this degeneration; then appear repeated fields and no ova, and again groups of ruined ova. In other portions there are numberless ova; each one could have done good work, now destroyed by waxy degeneration. In

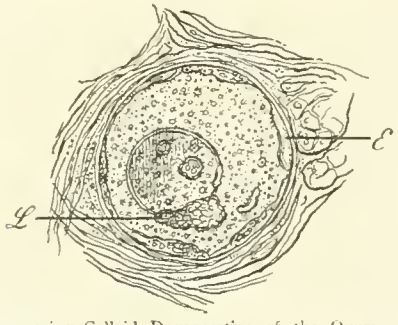

Fig. 7.—Commencing Colloid Degeneration of the Ovum. *L*, Lump of colloid material; there are similar lumps in the vesicula germinativa; *E*, flat epithelium in beginning colloid degeneration. × 600.

both ovaries the medulla is in myxomatous degeneration, yet crowded thick with colloid bodies. In one section, between the medulla and cortex is a Graafian follicle, the walls waxy, myxomatous tissue within, and this myxomatous tissue in a state of inflammation and crowded with colloid corpuscles. Outside of the follicle, the ovarian tissues are in intense oöphoritis and filled with similar corpuscles, while larger colloid bodies seem to crowd to the periphery; and amid them is the exhibition of ruined ova, all showing a wonderful history.

A most interesting study this the many ways in which ova may be destroyed, the various forms of degeneration, and the different degrees of destruction. Each section of these ovaries presents most important subjects for consideration, and they invite thoughtful study and investigation.

A yet more remarkable instance of colloid degeneration of the ovary: Mrs. R——, a young woman twenty-one years of age, with "pus tubes," interstitial pyosalpingitis. One section of the right ovary: intense inflammation of the cortex, and all around bright colloid corpuscles; not one ovum is to be found. Another section: no ova, colloid bodies, and blood-vessels in colloid degeneration. A third section: colloid degeneration of all the structures, blood-vessels closed, and walls in colloid degeneration. Left ovary: cortex in intense inflammation; abscess in the cortex; only one ovum is found, and both its yolk and its epithelia are in colloid degeneration.

In one of the most marked examples of myxomatous degeneration of the ovary, Miss E. Memmen, there is also colloid degeneration, and many of the ova are in the same degeneration. In one the whole ovum is reduced to colloid substance and protoplasm. In another, the epithelia waxy, waxy yolk, and the vesicula and macula colloid; another, the outside is in waxy degeneration, with colloid degeneration of the vesicula, and the macula reduced to protoplasm. In the midst of myxomatous degeneration is a Graafian follicle with waxy walls, and around it is intense inflammation, and near by are ova in colloid degeneration. Altogether it is a wonderful presentation.

It will be interesting to see the commencement of colloid degeneration represented in the next figure (Fig. 7). Colloid granules begin forming from a previously inflamed tissue; the granules grow larger, and form large masses, while there is a general infiltration of colloid corpuscles through the tissues. The patient was a Miss H——, thirty-five years old. She had an abscess in the left ovary, myxomatous degeneration of the right, then an endothelioma, gyroma, colloid formations, and waxy blood-vessels. The ova also present a scene of disease and destruction. In one, the yolk, vesicula, and macula are in colloid degeneration, and no epithelia can be traced; another, the epithelia are full of colloid bodies, and the yolk, vesicula, and macula are a mass of larger and smaller colloid formation with no normal structure left. Another ovum is only a vestige, showing it has been in colloid degeneration; then two more, almost destroyed by the same form of degeneration; and near by are all the wonders of an endothelioma changing to blood corpuscles; blood corpuscles rising out of this granular life matter, or protoplasm; and, more wonderful still, the oft-repeated sight of newly forming blood-vessels. Near this endothelioma is an ovum in the first stage of forming what is called a Graafian follicle. There are the spreading wall of the young ovum, the mysteri ous multiplication of the epithelia, the increasing activity of the vesicula and macula, and all the marvellous life changes in the process of the development of the ovum. But just when this wonderful little structure is taking on new life and new activity, it is stopped, blighted in its growth, petrified, fixed, callous, dead.

Such sad destruction of the growing ova I have seen in many instances. The young ovum is active in the wonderful processes of developing into a perfect human being, when, like a upas, comes this strange, this petrific degeneration, and all the life parts in the developing organization become apparently reduced to this yellow-like, bright, transparent colloid material. In one patient (Mrs. I. J. Hunt), besides the active young developing ovum already petrified, I could count seventy-eight bright colloid bodies crowding close up around the young ovum which had been so cruelly stricken, and thereby stopped in its process of development.

Fig. 8 shows colloid degeneration with pigmentation. We see the central parts of the ovum, the yolk, vesicula, and macula, are covered with colloid bodies accompanied by more or less pigmentation. The epithelia are also in colloid degeneration. Both ovaries in this patient were found in intense inflammation, each one containing an abscess. There were also peritoneal abscesses and interstitial pyosalpingitis. The patient, Mrs. A——, was twenty-eight years old, married, had never conceived, and was suffering so seriously that she could only seek refuge in a hospital. She complained of constant pain in the pelvis, and said

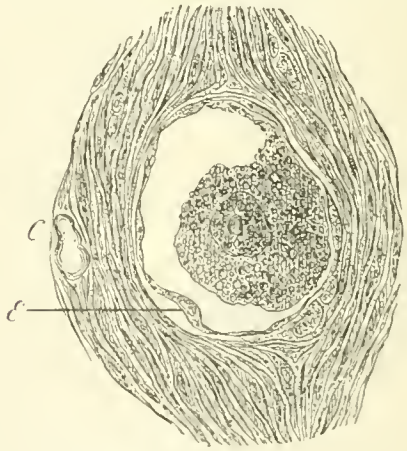

Fig. 8.—Diffuse Pigmentation and Incipient Colloid Degeneration of the Ovum. *E*, Detached epithelium; *C*, colloid corpuscle in the muscle layer. × 600.

she suffered so much that she could no longer endure it. The operation for removing the uterine appendages was performed at the Woman's Hospital of Brooklyn, in January, 1888. The "pus tubes" and ovaries were bound down by dense adhesions, and the adherent peritoneum contained a number of small abscesses. After being relieved of these hopelessly diseased struc-

tures the patient's health became excellent. I would say that the ovaries of this patient were remarkably well formed and well constituted; such as could develop hundreds of vigorous and life-giving ova. Gonorrhœa came!—not of long standing, but the infection seemed at once to affect the ova, and by some mystery they are all in colloid degeneration, while there are comparatively few colloid corpuscles found in either ovary. Sections of each one show not only abscesses, but large growths of endothelioma. The ova and blood-vessels are in colloid degeneration.

Fig. 9 is a most interesting example of colloid combined with waxy degeneration. Colloid corpuscles are in the epithelia, and they occupy a large portion of the vesicula, and apparently have destroyed the whole of the macula, while portions of the vesicula and of the yolk are in waxy degeneration. This ovum is in the midst of inflamed ovarian tissue. There are large ovarian cysts, the walls in intense inflammation, and filled with colloid corpuscles; other portions of the ovary are in intense oöphoritis. In many sections of the right ovary there are no ova. In other sections there are a few, and these in colloid or waxy degeneration; and of some ova there are only remnants of structure, many ova evidently having been destroyed. There is an endothelioma forming its seas and lakes of blood, a hæmatoma enlarging still more the enlarged ovaries and the cysts, with walls in a high state of inflammation. Also, in each ovary there are Graafian follicles, the walls of which are in waxy degeneration, and the myxomatous tissue within contains colloid corpuscles.

It was in the ovaries of this patient that gyromatous formations, or gyroma, were first recognized.[1] Any new growth or formation, or any morbid change of tissue, must necessarily cause in a patient pain, distress, and suffering, and more or less constitutional disturbance. As we know, even the formation of an abscess, which is a temporary change of only a small portion of tissue, gives more or less distress. This patient, Mrs. M. G——, once had healthy ova. Though only thirty-five years old, she had given birth to eight children, but the sepsis of the last confinement seemed to have infected every structure of the ovary, developing acute oöphoritis, gyroma, endothelioma, and finally a large hæmatoma or blood cyst; and probably the same sepsis destroyed all of the ova, and caused the colloid degeneration. She first came to the out-door

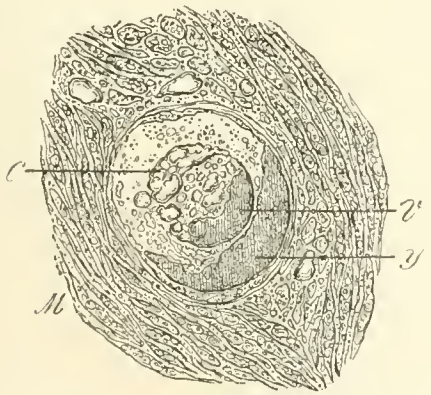

Fig. 9.—Combined Colloid and Waxy Degeneration of the Ovum. *C*, Colloid mass at the upper periphery of the vesicula; *Y*, lower portion of the vesicula transformed into a waxy mass; *Y*, waxy portion of the yolk. × 600.

department of the Woman's Hospital of Brooklyn, August, 1887, a mere shadow of her former self, emaciated, feeble, and suffering great pain. When she entered the hospital, she begged to be relieved of her suffering, and repeatedly asked that she might have an operation, and was disappointed at any delay. So weak was the patient, and so unfavorable her condition, that we did not think it possible for her to survive an operation.[1] Finally, to relieve her in some respects, the operation was performed; she made an

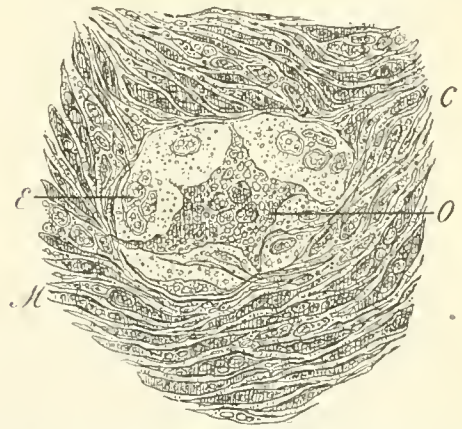

Fig. 10.—Beginning Transformation of the Ovum into Fibrous Connective Tissue. *O*, Yolk and vesicula germinativa, shrivelled and coarsely granular; *E*, embryonal corpuscles, sprung from previous epithelia; *C*, newly formed fibrous connective tissue entering the ovum; the capsule of the ovum is lost; *M*, inflamed smooth muscle fibres. × 600.

excellent recovery, was apparently in good health, and on returning home commenced at once her heavy household duties, working for a family of eight persons. Her husband said she had not been so well for fifteen years.

Fig. 10 is a remarkable presentation and suggests many subjects for thoughtful consideration. The ovum is atrophied and in waxy degeneration, yet the whole of both ovaries are in colloid degeneration. We see the inflamed muscle fibres around the ovum, and we can well imagine the advanced condition of disease when the muscle fibres themselves are inflamed; and if they are thus inflamed, or reduced to protoplasm, we may know that more advanced pathological changes will appear. We see that, amid the inflamed muscle tissue, new fibrous connective tissue is entering the ovum. It is progressive atrophy, and shows how many ova may gradually disappear from a diseased condition of the ovary. We see that the whole of this ovum is reduced to inflammatory corpuscles or protoplasm.

We find many interesting examples of atrophy, especially after ova have been reduced to fibrous connective tissue. This patient,[2] thirty-nine years of age, had been sick since she was twenty-five, and continued to grow into worse conditions, the pain increasing in severity, much of her time she was not able to be out of bed. She was at one time in the Massachusetts General Hospital, also under an eminent specialist of Boston. He informed her that her ovaries were diseased, but that an operation would be exceedingly dangerous. Subsequently, during the summer of 1888, this patient was in the Woman's Hospital of Brooklyn. She returned in the fall, and in November of that year I removed the diseased tubes and ovaries, and she has said many times since that "she was so glad that she had the operation, that before she did not expect to live, but now she had gained in health and strength." The ovaries were found diseased in every part; not only colloid degeneration, but a far advanced endothelioma was forming vast fields of blood; there was a gyroma in waxy degeneration, and in both ovaries there were found only the remains of a few ova.

[2] Miss T. W——, Medical Record, August 7, 1897, case lxxiii

The nature of colloid degeneration is not yet understood. We do not know its origin or the cause that produces it. Nor do we know the symptoms of colloid degeneration in the ovaries or how to diagnose it. We can only recognize in the patient the evidences of disease, suffering, and distress; but no special indications that point to or would prove colloid degeneration.

Thomas Bryant,[1] the great English surgeon, said: "Its true nature is not yet fully known." Moore says:[2] "As to colloid, pathologists have not yet agreed among themselves as to the diseases which should be included under this name; many authors speak of it as a variety of cancer." Lazarus Barlow,[3] demonstrator of pathology, University of Cambridge, England, says: "Colloid, mucoid, and hyaline changes are at present but little understood and therefore lack definiteness." Professor T. H. Green[4] says: "The chemical nature of colloid material is as yet unknown." Quain in his "Dictionary of Medicine," 1894, says: "Colloid, a peculiar morbid product resembling in its character glue or jelly, and found associated with cancer and other forms of new growths." If colloid material is of the nature of glue or jelly, why should it not mix more or less with the interstitial fluids, or "juices," of the ovary? Would it be possible for masses of glue or jelly to remain constantly in fluids, and have such firm outlines, and apparently such clearly defined boundaries? Would not glue or jelly be more or less changed by the continued presence of the animal fluids or succulent tissues? Yet here, in these countless numbers of colloid bodies or corpuscles, not one is found that is the least mixed with fluid, or in itself is the least changed.

Many eminent authors speak of colloid bodies or corpuscles as "drops," or "droplets of colloid matter." These "drops," or "droplets," must be wonderfully firm to retain their various shapes and sizes; but, what is yet more surprising, many of these drops or droplets show distinctly that they are composed of granules.

Sir James Paget[5] says: "The colloid matter is in different parts or in different instances various in consistence." Dr. J. C. Warren[6] says: "There is some difference of opinion as to the origin of colloid matter. Some think it is elaborated by the cell; others assume that it is exuded by the vessels." If it is elaborated by the cells, would not similar cells produce it in all instances? I believe colloid degeneration develops directly from protoplasm, as all other degenerations or new tissues are formed.

Delafield and Prudden[7] say: "Colloid degeneration is of frequent occurrence in certain tumors and in the thyroid gland, and occurs occasionally in other places."

We have thus far seen that in various diseases of the ovaries colloid degeneration is of frequent occurrence. The human ovaries give a sad record of this disease or degeneration. For the last few months, I have been carefully studying by high and low powers of the microscope sections of eighty-seven pairs of ovaries, and in the eighty-seven I have found the ovaries of forty-seven of the women in colloid degeneration. I marked down the names of each individual case; each one was a most interesting history, and all illustrated many important facts in the pathology of the ovary. So many instances did I see of colloid degeneration, and so destructive was this disease to the ova, that when in reviewing old sections which I had previously studied,[1] not recognizing colloid degeneration, when I would see marks "No ova," or "Few ova," I at once concluded there was colloid degeneration, and invariably found it to be the case; though ova are, in a measure, also destroyed by endotheliomatous growths, and by waxy degeneration; yet colloid degeneration seems the most peculiar and the most universally destructive of all degenerations. I have found colloid degeneration in the ovary when there were most serious forms of tubal diseases, and when there was no special disease of the Fallopian tubes. I have found colloid degeneration in cases of the most intense oöphoritis; and I have found cases of intense oöphoritis, even bordering on suppuration, when there was no colloid degeneration. I have found colloid degeneration in some cases of abscess of the ovary, and in other cases of abscess there was no colloid degeneration.

In some cases when I have removed the uterine appendages for intramural fibroid tumors, I have found colloid degeneration of the ovary, and in other cases of intramural fibroid there was no colloid degeneration. In a feeble and anæmic woman with an intramural fibroid weighing nine pounds, there was no colloid degeneration; and in another suffering the same way, and with an intramural fibroid weighing thirteen and one-half pounds, there was colloid degeneration.[2] Then again there were small and large fibroid tumors, some with colloid degeneration, others without.

Colloid degeneration differs very greatly in different ovaries both as to the extent and the degree of degeneration. It differs also as to the size of the bodies or masses of colloid material, some being many times larger than others.

Colloid degeneration seems not only to destroy normal tissue, but it somehow has the power of displacing and destroying other growths and other forms of degeneration. An endothelioma around and in an intensely inflamed cyst wall, I have found almost destroyed by colloid corpuscles. Again, with the wall of the cyst in full waxy degeneration and crowded with colloid corpuscles, one could see that the waxy degeneration was gradually disappearing and being displaced by the growing colloid formations. In many cases of waxy degeneration, I have watched the glimmerings of new-forming colloid corpuscles, and could see that colloid degeneration was coming with its singular powers of destruction.

In another part of this paper I mention the instance of colloid corpuscles being in the endothelia of an endothelioma. A most extreme example of this was in the case of a patient who came to see me in 1887, suffering greatly from a complicated condition of disease of the pelvic organs, till the woman had become partially insane. After the operation of removing the diseased uterine appendages, the patient was not only improved in physical health, local and general, but had very much more normal mental conditions. In the examination of a section of the ovaries at that time I recognized the acute intense oöphoritis, the gyroma, the endothelioma, and the diseased ova, but only lately have I recognized the magnitude of the colloid degeneration. In an endothelioma in these ovaries, instead of granules merely of colloid matter, there were, all through the endothelioma, large bodies of colloid substance; and the endothelioma was somehow mysteri-

[1] This valuable collection of specimens I had prepared with great care and some expense for the museum of the Woman's Hospital of Brooklyn. They were collected in 1885–90, and the specimens are all from patients who were in that hospital. Subsequently the board of trustees of the hospital, by a vote, gave them again to me, but I intend some time to pass this valuable collection over to some college or to some hospital museum.

[2] Both these tumors were removed by hysterectomy, one suprapubic, the other total. Both patients recovered. (British Gynæcological Journal, February, 1898, p. 502.)

ously being destroyed by these colloid formations. I have recognized, in other instances, the destruction of an endothelioma by a growing colloid degeneration.

Colloid degeneration as yet presents a wonderful mystery, and it seems completely to destroy the ova in the ovaries of even the youngest women. I have found colloid degeneration in the ovaries of young women eighteen and twenty years of age, and equally in women who were forty-eight, forty-nine, and fifty-three years of age. It is not an understood disease, and each individual instance is of great interest. It, like all other pathological subjects of the ovary, should be studied in connection with the clinical history of the patient. The whole subject of the pathology of the human ovary is becoming more and more vast, and of more and more importance. When I first turned my attention to it, I imagined in a few weeks I could understand all about the normal and pathological structure of these little organs. More than twenty years have passed, and I find more than ever to study, to wonder at, and to consider seriously. Each individual slide, or each section of the ovary, would seem to demand hours, and some even years of study, and then all is not understood, there is so much in each one. And when I look at the wondrous changes, the marvellous developments and growths of diseased ovaries, and then at the infinite perfection of each minutia of normal ovaries, I can only bow in adoration, recognizing a Supreme Power and an Infinite Intelligence. It would seem there were enough wisdom, design, and painstaking in the construction of the ovaries to have created a world. They are the representative links of human history.

Dr. G. E. Herman, of London, author of a large work on "Diseases of Women," wrote me on June 16, 1898: "I have read many of your papers with much interest; more especially a recent one on 'Diseased Ova.' I think in studying this subject you break new ground, but I think a necessary preliminary to right judgment upon morbid conditions of the ova is a knowledge of the changes in the ova which depend upon age simply, and are not morbid." [1]

It would be exceedingly interesting if one could have the opportunity of studying normal human ovaries, and to note "the changes in the ova which depend upon age simply, and are not morbid." In my microscopical studies, I have been able to recognize in the ova only changes from disease, and in most instances these changes were in the ovaries of quite young women, nineteen, twenty, and twenty-one years old. Still, as far as I have had the opportunity of noting a few instances of normal ova between the ages of nineteen and fifty-three years, I could observe no change that could be attributed to age, or that might come from advancing years, nor have I been able to observe changes in any ova that were not clearly from infection, or some form of degeneration arising therefrom. The changes—pathological and otherwise—of ova, as of other structures of the body, are not so much from age as from infection.

I was once privileged to examine sections of the ovaries of a woman near seventy years of age, removed post mortem. These ovaries did not give evidence of any change from age, nor were there any special indications of disease, except a few colloid corpuscles in the cortex. The ova were in apparently normal condition. I give a drawing from the ovaries of this woman near seventy years of age (Fig. 11). I have seen sections of the ovaries of a girl eighteen years of age, and the ova were more changed than in the ovaries of this woman near seventy years old.

Why should the ova change from age any more than other anatomical structures of the body? Do the muscles change with the passing years? Do they not look the same in the old and the young? From a specimen of muscle tissue can one decide the age of the individual? In the ovaries of this old woman, the muscle structure, under a power of five hundred, did not show any apparent change. The interlacing fibres were apparently as natural and beautiful as those presented by a comparatively young woman.[1] Nor was I able to recog-

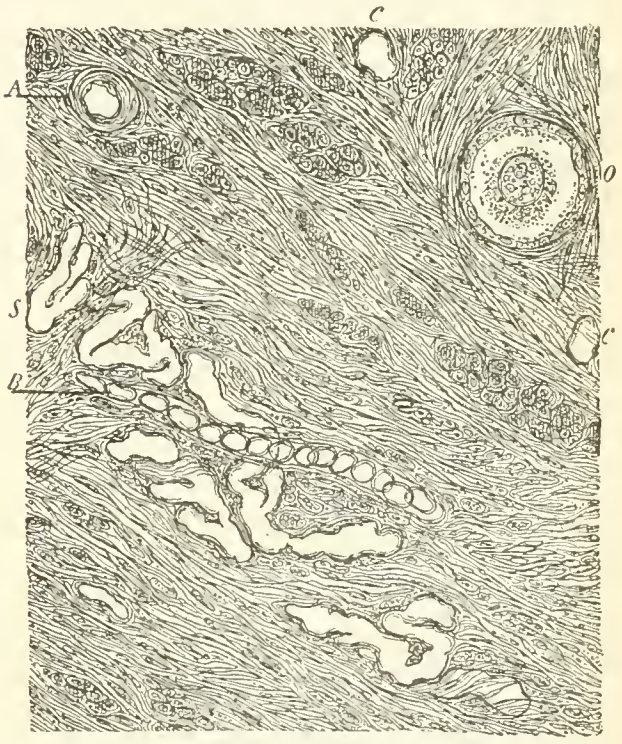

FIG. 11.—Cortex of the Ovary of a Woman Seventy Years Old. *S*, Convoluted structureless membrane, embedded in fibrous connective tissue; *O*, ovum, yolk shrivelled; *A*, artery in transverse section; *B*, capillary blood vessel in longitudinal section; *C*, *C*, colloid corpuscles. × 500.

nize, in the ovaries of this old woman past seventy years of age, any change in the blood-vessels, for instance. The walls had not changed to fibrous connective tissue, as we might imagine, nor was there any form of degeneration of the blood-vessels, which we so frequently find in the diseased ovaries of many young women, and, which changes must necessarily interfere with or render less active the circulation of the blood. Not one vessel in the ovaries of this old woman had become incapable of work, and, what was more remarkable, in all the sections that I examined there was not one instance of a diminution or closure of the calibre of any of the vessels, not one instance of endarteritis obliterans; yet I have found diseased blood vessels, a diminution of the calibre, and complete endarteritis obliterans in the ovaries of many young women, and in the ovaries of women of all ages from disease.

And in the ovaries of this old woman no part of the organs was so worn and diseased that it had degenerated into cysts; yet in the ovaries of the many young women I have found the whole ovary riddled and destroyed by cyst formations.

What was further remarkable in these ovaries was the structureless membrane, which often in the diseased ovaries of young women has shown such won-

[1] It has given me great pleasure to present from time to time my investigations to the kindly consideration of the medical profession. No profession stands higher, there is none I more profoundly honor, and none I regard as more profoundly learned. It was the great and good men of the medical profession in this country that stood by the right in that uncalled-for and most cruel persecution against the Woman's Hospital of Brooklyn a hospital that was doing such beautiful and excellent work. My debt of gratitude to these honored men is unceasing. I could again and again thank them by name, for their most noble magnanimity.

[1] See Fig 3 American Journal of Obstetrics, vol xxxvi, No. 2, 1897

derful pathological changes, developing those curious rormations known as gyroma, which in so many instances have proved to be the source of serious trouble and suffering; yet in the ovaries of this woman, past seventy years of age, the structureless membrane was in a normal condition. For thirty, thirty-five years, or perhaps longer, this structureless membrane had lain quietly, not changed, inflamed, or enlarged, but just as it would be in the healthy ovaries of vigorous young women.

It is disease that does the damage and works the marvellous changes in the ovary. One young girl twenty-one years of age was perfectly formed and apparently healthy, yet I find in the ovary intense oöphoritis, gyroma, endothelioma, and there is colloid degeneration through every part, which has destroyed the ova till there are but few left: one ovum has the macula and vesicula reduced to granular matter, and is in a crowd of corpuscles; another ovum with the vesicula and epithelia waxy, while colloid corpuscles are crowding into the ovum and close around it. In another section of the ovary is a group of four ova, all in waxy degeneration; next a group of four in colloid degeneration; some few scattering ones are almost gone, and there is a shower of colloid corpuscles all around. There was not only this wonderful showing of diseased ova and colloid degeneration, but this young girl of twenty-one had salpingitis. The folds of the mucosa of the Fallopian tubes were in most places completely destroyed by masses of inflammatory corpuscles, and even the whole muscle wall of the Fallopian tube was in colloid degeneration.

As a little further record, or other instances: Katie ——, eighteen years old, showed many different groups of ova almost destroyed by colloid degeneration, while around were imperfect remnants of colloid ova. In Mrs. F—— was seen an endothelioma nearly destroyed by colloid corpuscles, another endothelioma breaking down into intense inflammation; from periphery to cyst wall there was not a sign of an ovum. Another section found the ova almost gone, and the mucosa of the Fallopian tubes destroyed by inflammatory corpuscles. In Miss Polly P——, nineteen or twenty years old, repeated sections show colloid degeneration and ruined ova with a cyst wall intensely inflamed, becoming filled with colloid corpuscles, which are apparently destroying an endothelioma. In the midst of colloid material, ova are in waxy degeneration.

Another young woman, Miss M——, showed a waxy ovum almost gone in the midst of colloid degeneration. In another field were eighteen ova surrounded by colloid corpuscles, and colloid corpuscles thickly strewn all through the cortex; a waxy ovum with colloid corpuscles in it; in another portion of the cortex, not one ovum could be found. Thus constantly were presented wonderful pictures of the destruction of ova in the midst of colloid corpuscles. In this patient both tubes were in a state of interstitial suppurative salpingitis, and both bound to the ovary by inflammatory adhesions. In another young woman were many bright colloid corpuscles, and not one normal ovum! Sad, to see the ovaries of young women so diseased! All through these ovaries were intense inflammation and abnormal growths, and around were showers of colloid corpuscles.

Another young woman, Mrs. H——, only twenty-one years of age, was in even worse condition, both as to ovarian and tubal disease.[1] Mrs. U——, a young woman, sought relief because she wanted to be the mother of children. There are intense oöphoritis, endotheliomatous growths, and not one ovum is found—all destroyed! A young girl, Miss Mary M——, scarcely twenty years old, presented colloid degeneration, large endothelioma, acute oöphoritis, and no ova; Miss S. S——, twenty years of age, pus tubes, whole ovary in intense oöphoritis; Miss A. M——, twenty-one years old, the same conditions, and not a single ovum; Miss T——, near forty years of age, colloid degeneration and not one ovum; Mrs. C——, twenty-three years old, pus tubes, abscesses, colloid degeneration, and no normal ova; Mrs. N——, a young woman past thirty, married, sterile, with years of suffering, inflammation, suppuration, colloid degeneration, myxomatous degeneration, and no ova.

So I could give the history of many young women in whom the ova were gone or destroyed by colloid degeneration. I do not tell half the marvellous things that are constantly being revealed. We do not know the wonders or understand the significance of colloid degeneration. It seems the most wonderful of all forms of degeneration, and apparently has the power of overwhelming and destroying every other. I am convinced that colloid degeneration plays a large part in the pathological condition of many ovaries. This degeneration presents a wonderful mystery. I find the most interest and the most profit in studying the pathological conditions of the ovary in connection with the clinical history of the individual cases. A knowledge of the clinical history seems a necessity not only for the clear and full understanding of the case, but in order to have the clearest insight as to the nature and the causes of the pathological changes.

I am further convinced that the removal of such diseased ovaries and tubes as are mentioned in these various forms of degeneration is the salvation of the individual and the saving of the lives of many sick women. The diseased ova in these young women were, in most cases, if not every one, caused by some outside infection, in one way or other. Besides, every one of these young women was, so far as I could learn, before this infection apparently healthy and with sound constitution, and life's prospects were opening before each one with promises of joy and happiness. The infection came, and all their bright, beautiful prospects were destroyed.

These investigations only show a little more fully the nature of their sickness, and still more how it was not only blighting their dearest hopes but destroying their lives. Should not such diseases in young women be prevented? Should not young women be instructed and protected?

One young physician said to me a short time since: "What is the use of studying these intangible subjects? What we want to know is, when and how best to operate." Do we not know when and how best to operate, when we know the momentousness of the disease, and can weigh all the solemn responsibilities? I studied because I wanted to know, and wanted to learn the best thing to be done to help these suffering young women. I believe many young women have been lost from a lack of the recognition of all the seriousness of their disease, and the necessity of giving immediate relief. Many more have perished in this way than by having the ovaries removed when some may have imagined there was no necessity, or there was no immediate danger, or there was possibly some other way of relief. As I said in 1886,[1] "the fault is not with the surgeons who are trying to help the sick women, but with those who have gone before."

I have never been able to believe that ovaries have ever been removed when it was not necessary; even by Battey, who professed to remove normal ovaries for constitutional conditions, yet from a study of his cases I believe in each instance the disease of the organs themselves demanded their removal. I believe many women have died from not having hopelessly diseased tubes and ovaries removed. I said further in 1886:[2]

[1] MEDICAL RECORD, August 25, 1886, p. 100.

[1] MEDICAL RECORD August 21, 1886.

[2] Ibid

"I have never seen the ovaries removed in a single instance, but they were more diseased than the symptoms led me to suppose," and that "removing diseased uterine appendages is not unsexing a woman, it is restoring her from helpless invalidism to all the possibilities and opportunities of life and labor. It is not taking away her capability of having children — that has already been done by the disease— it is only removing a cause of suffering and of threatened danger." We will find that the disease makes more serious conditions and more profound constitutional disturbances than does the absence of these organs.

In the careful study of many ovaries, by the aid of high and low powers of the microscope, I have never yet seen an ovary of which I could believe a part could be left with advantage to the patient. I rather believe, when part can be left, none should be taken.

## CONGENITAL HERNIA OF THE UMBILICAL CORD.

By W. B. COLEY, M.D.,
NEW YORK.

CONGENITAL hernia of the umbilical cord develops before the falling of the cord, and is due to defective development during fœtal life. Lyndfors estimates its

CASE I.—Before Operation.

frequency as 1 to 5,184. The size of the hernia varies from a small bulging at the base of the cord—sometimes described as hernia of the root of the cord —to a complete eventration in which nearly all the abdominal organs are found in the hernial sac. In this form of hernia there is no true sac, the protruding viscera being coated with the myxomatous tissue of the cord, and covered by its amniotic layer, the latter being continuous with the skin and the peritoneum.

The prognosis is very grave no matter what form of treatment be adopted. Until comparatively recent times, the treatment of this variety of hernia was entirely expectant, an attempt being made to retain the rupture by means of compresses and bandages. Of

CASE I.—After Operation.

twelve cases collected by McDonald treated in this way, nine were fatal; while out of nineteen patients treated by laparotomy only one died.

The present cases are (with the exception of one of small size) the only ones seen by the writer in nearly ten years' experience at the Hospital for the Ruptured and Crippled. The accompanying photographs, taken twenty hours after birth in one case and twenty-four hours in the other, give a very accurate idea of the condition.

CASE I.—The tumor itself, about the size of a large orange, is covered only by the dilated tissues of the cord. Operation was performed in July, 1889, twenty-two hours after birth. The projecting portion of the cord was cut off on a level with the hernial tumor; the outer layer of the tissues of the sac was peeled off as far as possible; the edges of the skin at the junction of the root of the cord were then freshened and by a series of silkworm-gut sutures brought together after the hernial tumor had been reduced. The peritoneal cavity itself was not opened; at the lower extremity a small opening was made to allow free drainage in case of any sloughing of the tissues. The abdomen was then firmly supported with compress and bandages. The time of operation was thirty minutes.

CASE II.

A small quantity of chloroform was used as the anæsthetic. The child made a very good recovery. The wound was dressed every two days by Dr. Preston I. Satterwhite, and to his careful after-treatment is largely due the successful result. Case II., taken two months

later, shows only a slight bulging, which is slowly diminishing.

Case II.—A child aged twenty-four hours was brought to the hospital just one week after the case just described. The tumor was much larger than that in the first case, being fully as large as the child's head and partly made up of fluid. An incision was made into the sac, evacuating about half a pint of straw-colored fluid. The sac contained the liver and most of the large and small intestines, and in view of the very small size of the abdomen it was quite impossible to reduce the contents. The wound was closed, and the prognosis was regarded as absolutely bad, but three weeks later Dr. Satterwhite found that the child was still alive.

## HEADACHES DUE TO EYE STRAIN.[1]

By JAMES COLE HANCOCK, M.D.,

BROOKLYN, N. Y.,

OPHTHALMIC SURGEON TO THE EASTERN DISTRICT HOSPITAL.

Gentlemen: During the ten minutes allowed me this evening I want to call your attention to the symptom headache, than which there is probably not one more frequently encountered, and there are certainly few giving more discomfort and resisting the ordinarily employed treatment longer, the last being often due to a lack of appreciation by the physician of the true direct or indirect cause, and often to a so-called "headache habit" in cases of long standing, that sturdily resists even proper treatment for a varying length of time, usually extending to the limit of our patience and frequently beyond it.

The headaches caused by eye strain, and it is to these I want to ask your notice especially, are of far more frequent occurrence than is generally supposed; and this is mainly due to the fact that in hypermetropia, the most frequent cause of these headaches, the visual acuity is often as great and sometimes even greater than where there is no error of refraction at all. Due to this it is that so many of our school children pass satisfactorily the eye tests in vogue in the public schools to-day, but continue to suffer from headache and other symptoms attending eye strain.

Hypermetropia, astigmatism, insufficiency of muscles, myopia, and last but very important, the so-called accommodative asthenopia due frequently to disturbances of the general nervous system and not infrequently to uterine disorders especially in young women, are the conditions giving rise to most of the headaches due to eye strain, and I have arranged them with regard to their relative frequency as I have found them. The generally accepted normal eye is so constructed that parallel rays—and all rays are considered as such that come from a distance equal to or greater than six metres—are brougth to a focus at the fovea centralis in the retina without any muscular effort or aid. When a normal eye is being used for distance the ciliary muscle is lax, the lens compressed in its capsule, the vision of such an eye being quite as acute when the ciliary muscle is completely paralyzed with atropine as when the muscle is in the natural state. When a change to the near or so-called reading distance is made, the ciliary muscle at once comes into action, drawing the choroid forward, thereby loosening the lens capsule and allowing the hitherto compressed lens to thicken itself by its inherent elasticity, thus shortening its focus and bringing the diverging rays from a near object to a point upon the retina.

In hypermetropia, or so-called "far-sightedness," we have to deal with an eye shortened in its antero-posterior diameter, hence even parallel rays must be forcibly focussed upon the retina, as the latter lies forward of the focal point of the lens. In such an eye, then, the ciliary muscle is in constant action except during sleep. It becomes over-developed and very irritable. The eye, as you see, is under a constant strain, and you can readily imagine the result: headache almost always.

The astigmatic eye is the one in which there is a difference in the refraction of the horizontal and perpendicular meridians of the cornea generally, and sometimes of the lens or both. One meridian may be normal, the other hyperopic or myopic; both may be hyperopic or myopic in different degrees, or one may be hyperopic and the other myopic, the last condition almost always causing headache and being very difficult to correct. Astigmatism usually causes headache, and invariably when present in marked degree.

The main factor in the causation of headache due to muscular insufficiency is the unceasing and often abortive effort of the weak muscle to contribute its proper share of muscular force to maintain the equilibrium necessary to binocular vision.

In myopia the eye is elongated antero-posteriorly. The rays coming to a focus upon the retina of such an eye must be divergent upon entering, hence objects are held close to the face. The ciliary muscle in these cases is usually small and has little call upon it. The cause of headache here is extreme and constant action of the internal recti muscles, convergence due to the near point at which objects must be held to be distinctly seen, calling them into use with every visual effort. Myopia is usually acquired in close application at school, etc., and is practically unknown in uncivilized communities, while hypermetropia and astigmatism often seem to be hereditary. Myopia has a tendency to increase, and the condition requires very careful watching.

Regarding the last cause in the list, that depending upon a deranged state of the nervous system in general, and the generative organs in particular, much might be written, but it seems best to leave it to those who have made these conditions subjects for general study. The resulting eye symptoms and the headaches are often severe, and we frequently find upon careful examination that the eyes are quite normal with regard to their refraction. These are, of course, cases for the neurologist or the gynæcologist, and proper treatment at their hands usually results in the disappearance of all eye symptoms.

To sum up: The conditions bringing about a so-called "eye headache," it seems to me, are an undue stimulation of the nerve centres of nerves supplying the intrinsic and extrinsic muscles of the eye, causing a reflex vasomotor action referred to the meninges and producing congestion.

It is also suggested that confusion of images plays the important part in the causation of these headaches, and that there is no known instance in which they have followed excessive use of other than ocular muscles. I believe the confusion of images may be an important contributing cause, but it seems to me that the "muscular reflex" plays the most important part. While I fully admit that continued muscular exertion in general does not cause headache, I think it probable that excessive and continued contraction of any muscle supplied by cranial nerves would do so. Obviously, except in the case of the ocular muscles, it is difficult to gather evidence in support of this theory.

In all the conditions mentioned above, even including those due to purely reflex causes through the nervous system—by way of exclusion—a thorough examination of the eyes should be insisted upon, and this can be thorough only when the ciliary muscle is completely paralyzed.

[1] Read before the Medical Society of the Eastern District Dispensary and Hospital, August 30, 1899.

In hypermetropia glasses should be worn for reading and other close work only, unless distant vision is impaired; in myopia for distance when present in marked degree, and for reading when the book is habitually held nearer the face than thirteen inches.

For muscular insufficiency prisms are worn and the weak muscles exercised. Operations are often necessary.

In astigmatism glasses should be worn constantly for here a complete correction, even temporarily is quite impossible.

43 Cambridge Place

## LIP-READING—AN AID FOR THE INCURABLE DEAF

By Mrs. CORA D. GORTON

NEW YORK.

According to late statistics, the number of deaf people under the age of thirty years is enormous While we realize what this implies for those who have not yet reached their prime in life, it is encouraging to know that a way is open to them by which they may still enjoy the privileges which are rightfully theirs.

The recent improvements in the treatment of aural diseases have restored many deaf people to spheres of usefulness, but there still remains an army for whom treatment is of no avail. Such people are seriously handicapped in all the walks of life, and many who possess remarkable natural talents are prevented from exercising them through their absence of hearing. This defect also debars them from participating in the social features of life, and imperceptibly, though surely, they become melancholic, hypersensitive and suspicious, leading a most unhappy existence. It is true that such mechanical contrivances as audiphones, fans, tubes, etc., offer to deaf people considerable improvement in hearing, but the extreme sensitiveness of such people prevents their using aids of this kind

How, then, are these people to be made to hear, after having been dismissed as incurable by a competent aurist? The question finds its answer in lip or speech reading. This science, at the present day, is no longer a theory, but something grounded upon established principles. The experimental age is past, and we realize with satisfaction the results obtained from the perfect systems now in use.

That the possibilities of this means of communication were recognized years ago is known by a statement of Dr John Bulwer's (1648), in which he speaks of "the subtile art which enables one with an observant eye to hear by watching the movements of the lips." The work of reducing it to an art, by systematizing and arranging it upon scientific and phonetic principles, is of more recent origin, and in its advanced state does great credit to the ingenuity of man and comes as a boon to the deaf, enabling them again to participate in the world's activities as people of understanding and intelligence.

We have so commonly regarded the sense of hearing as the only medium through which spoken language is understood, that for some people to realize the possibility of reaching the same result through other means may appear difficult. It is readily accomplished, however, by educating the eye, the sense of sight becoming unusually acute and taking the place of the aural sense.

When we recognize the positions and actions of speech, we are reading speech. In its accomplishment, both a mechanical and an intellectual process is exercised. The sight may be trained to carry to the brain actions of the organs of speech, and the brain associates ideas with them. Facility requires not only a quick and trained eye, but a degree of intellectual alertness, to resolve doubts instantly when possible cases of ambiguity arise, there being a vast number of words which appear alike to the eye of the speech-reader, words, for instance, beginning with the labial consonants *p*, *b*, *m*, and the linguals *t*, *d*, *n*. Such words, when presented separately, are to be distinguished with difficulty but the mind of the reader is at once made certain when they are recognized in their association with other words in the sentence. With unconnected words there is no context to assist the mind. The imagination is an aid to comprehension, and guessing oftentimes supplies doubtful words in a sentence in which two or three of the leading words are recognized. There is more to be seen by the reader than the mere moving of the lips, the position of the tongue, and the size and shape of the aperture of the mouth. There is the brow expression, whether it be contracted, elevated, or passive. He observes much that is important to his understanding from the expression of the eye and the unconscious movements of the head, the affirmative and negative nods. Perhaps one short sentence may contain a number of facial expressions other than those produced by the muscular activity of the mouth.

Do you imagine it difficult to be obliged to watch so much at one time? In learning to play the piano, for instance, you could see at first but one note at a time on a sheet covered with them Then, through practice, your sight was trained to embrace two, four, and more, until shortly your eye, in a single glance, recognized correctly chords of eight and ten different notes, including marks of expression and even read in advance whole measures of notes. The child wonders at his struggles with the first short words, after he has learned to scan in a glance and with perfect ease, a lengthy paragraph.

So with the speech-reader He grows unconsciously to note every mark of facial expression Through experience it becomes no tax upon the memory Even in the almost entirely blank faces of some speakers, and with the impediments furnished by heavily mustached mouths, there are always expressions and aids to be found, when one knows where to look for and how to interpret them. To expert readers whole sentences appear as one long word, for they learn to take it from the lips as a whole rather than to analyze it into its constituent parts.

How important to deaf people is such a knowledge of the art of reading the lips need not be demonstrated. One who has become a proficient reader often passes among strangers as an intelligent hearing person. It renders the social position, not a memory of something connected with a happy past, but a continued realization of the same. It releases one from that mental strain and suffering often produced from a sense of isolation too well known to the deaf person, a state of painful existence of which the fortunate hearing person cannot conceive.

The art is of material benefit to partially deaf people as well, in that the eye may catch the words the person fails to hear, and the combination of both senses renders conversation intelligible, even at a great distance.

Age, as a rule, makes but little difference in the acquirement of this language. My experience as an instructor proves that with a fair degree of intelligence and an ordinary vocabulary of vernacular language, the art may be acquired at almost any age in life; the pupil of fifty or sixty years other conditions being equal, will show as favorable progress as the much younger one.

While the methods are acquired in comparatively few lessons, much after-practice is necessary to insure proficiency. The pupil first learns to read his teacher's lips, then those of his family and the people with

whom he is more constantly associated, and lastly those of strangers

The tête-à-tête conversation is always easier for the beginner, but with experience the eye becomes accustomed to read general conversation quite as readily. While a few acquire a fair knowledge of the science of speech-reading intuitively, after many years of hopeless deafness, its accomplishment is much more rapid and satisfactory when systematic instruction is received.

The accomplishment of speech-reading is the addition of sunshine to a life which has been clouded by an impairment of hearing.

52 West Thirty-eighth Street.

## Progress of Medical Science.

**Cystinuria.**—In a study of cystinuria completed in the September number of the *Annales Génito-Urinaires*, Moreigne presents the following conclusions: (1) Cystinuria is an affection, or rather a particular and extremely rare condition of the organism which owes its name to the presence in the urine of a body of special nature, cystin. (2) The pathological importance of cystin depends upon the troubles which it may mechanically produce, it generally occasions nephritic colic by the elimination of cystinic gravel, and in certain cases it forms calculi in the bladder. (3) The urines which have been examined are acid, but slightly colored, having a greenish-yellow tinge, and generally depositing cystin in a sediment, under the form of hexagonal plates. In a word, they offer the common features of urine of cystinurics whose urinary apparatus is in good condition. (4) In the absence of certain influences, such as that arising from the ingestion of salicylate of sodium, the urine of cystinurics does not generally give rise to a deposit of uric acid along with the sediment of cystine. (5) The deposits, gravel or calculi of cystin, are generally accompanied by tyrosin. As to leucin, it remains in solution in the urine (6) Uric acid is found in the cystinuric urine in quantities notably greater than normal, other things being equal, and does not vary in inverse ratio to the quantity of cystin, contrary to the opinion put forth by some authors. (7) All the results of analysis tend to show that cystinuria is characterized by a state of the economy in which the nutrition processes are slowed. There is diminished activity in the intra organic exchanges, or again, under another form, there is exaggeration of the anaerobic life of the cells and partial arrest of the oxidation processes This deduction, the author says, is confirmed by different facts, the chief ones of which he goes on to specify.

**Phototherapy** — Valdemar Bie, of Copenhagen, gives an account of Finsen's phototherapy (*The British Medical Journal* of September 30th), illustrated with a double plate showing cases of lupus before and after treatment, and pictures of the instruments in use for sunlight and electric-light treatment He says in regard to the results of concentrated rays: "The principal advantages of the method are, besides its reliability, its excellent cosmetic results, the infrequency of relapses and their slight extent, and the fact that the treatment is painless. The good cosmetic results are due to the fact that there is no destruction of tissue, healthy or diseased. It is for the same reason that the results in respect to relapse are so favorable. One may without harm treat both the diseased tissue and the apparently healthy surrounding skin until one is fairly sure of having destroyed all the disease germs. When the patient has been treated till there are no distinct nodules of lupus to be seen, at that moment the treatment is discontinued till the swelling and redness of the skin have disappeared, so that it is easier to determine whether anything is left of the disease or not. If there is nothing visible the patient is still kept under observation. Many have, however, to be submitted to a second course of treatment Whether the nodules which develop are the result of recurrence, or whether they could not earlier be recognized as lupus nodules, is a matter of little consequence in itself. The principal thing is that there have always till now been a few scattered nodules which disappear after a short further course of treatment If the treatment is carried on for some time after the last nodule of lupus seems to have disappeared, recurrence would be more surely guarded against The fact that the treatment is discontinued as soon as we think it justifiable to do so is due solely to the desire to save the time and the money of the patients as far as possible. Inasmuch as the efficacy of the treatment is absolutely certain, and the patients, on account of its painlessness, are very willing to submit themselves to a second course, a recurrence is not nearly so serious a matter as it is after the older methods of treatment."

**The Restoration of an Entire Tibia Necrotic from Acute Osteomyelitis.**—In the *Annals of Surgery* for October, 1899, Dr. Cushing reports a case of osteomyelitis, with necrosis of the tibia, in which a successful result was obtained by removal of the dead shaft of the bone, and he summarizes as follows the indications for treatment in similar cases: To save the patient's life and relieve pain by immediate operation to establish free drainage, the medullary cavity should be opened, pressure relieved, and infection checked. If the bone dies, as it usually and rapidly does in the course of a few days, it should be removed. The most favorable time for removal is when the periosteum and the granulation tissue are in their most active regenerative stage, but before the process of calcification of the bone trabeculæ has enclosed the sequestrum within a compact dense shell of involucrum. This point is to be determined by frequent examination of sections of the periosteum with the microscope It is indicated by the presence of numerous fibroblasts, osteoblasts, and small trabeculæ in which lime salts are beginning to be deposited. Clinically, it can be recognized by the slight crackling sensation appreciable as the periosteum is incised, and due probably to the crushing of the trabeculæ by the knife The periosteum at this stage resembles granulation tissue in color, density, and vascularity. Macroscopically, there is no appearance of ossification. Bone will be formed from this elastic, flexible periosteal layer This stage in the case reported was probably reached in the seventh or eighth week of the disease. At this stage the necrotic bone should be removed by incising the periosteum in the long axis of the leg and shelling out the sequestrum. The periosteal sheath remaining should be closed by suture, leaving a solid cord or mass of periosteum buried in the centre of the leg when in its most active bone-producing condition If areas of calcification of any extent of thickness are found adherent to the inner surface of the periosteal sheath they should be dissected off. The superjacent soft parts and skin can be closed by suture. The utmost care and most efficient means should be used to render the operation an aseptic one, for primary union is important. The new bone is formed rapidly, apparently in from eighteen to twenty-four days, when the operation is performed at the time indicated. At this time ossification is so far advanced that the new bone is rigid. If the operation is performed too early, the growing periosteum is apparently injured and its growth interfered

with, if too late, a rigid bony involucrum makes the removal of the sequestrum more difficult and gives rise to the formation of a cavity that it is difficult to close. A radiograph in the case reported demonstrates that the medullary cavity is re-formed in the new bone The shaft of the bone is easier to restore than the epiphysis.

A Case of Ruptured Aortic Aneurism and Gumma of the Heart at Twenty-Six Years of Age.—Shaw reports in *The Lancet* of September 23, 1899, the case of a lighterman, twenty-six years old, who came under observation in a state of collapse. He had started work apparently in perfect health and spirits, with the exception of a slight cold that he had had for three weeks He was a singularly steady man, and had always been in good health. The work was fairly heavy, that of carrying frozen carcasses ashore, but the man had worked as usual for about two hours and a half when he was noticed to sit down, apparently in a faint His head was held between his knees for half a minute or more and he revived, but soon he fell on to the deck, again unconscious When the man came under observation he seemed to be conscious, but he was blanched and considerably collapsed He kept crying out about the pain in his abdomen and he asked not to be touched. The abdomen at first was rigid but afterward relaxed and the man was rolling about in great pain which was localized to the lower part of the left chest. There were, however, no corresponding physical signs The pulse was barely perceptible, 140 to the minute and irregular The heart could not be heard. The chest seemed to be resonant, and the entrance of air everywhere good The pupils were equal and only moderately dilated. A small bowel movement was passed involuntarily. Twenty minims of brandy were injected hypodermically. As the man was only taking gasps of breath, artificial respiration was performed and oxygen administered. Brandy was again injected, but the patient died within ten minutes after coming under observation and less than an hour from the time he was taken ill. On further examination after death the cardiac area was found to be increased by about one finger's breath in every direction beyond normal, although the chest indicated considerable emphysema. There were no signs of previous illness, and no scars on the legs or on the penis. It was stated by the patient's family that he had never had a day's illness, and no definite syphilitic history could be made out. The patient had three healthy children. He was fond of rowing, and was out training for a race only two days before his death Upon post-mortem examination the pericardium was found to be tightly distended and full of blood, and at the top of the pericardial sac there was a narrow slit, about one-sixth of an inch in length, opening into a saccular aneurism. This was about the size of a hen's egg projecting forward and to the right from the first part of the aorta over the top of the right auricle and pressing slightly on the right bronchus. The innominate artery opened out of it at its base. When opened, its walls were found to be thin and smooth and to contain only recent blood-clots. The cavity communicated with the aorta by an aperture three-quarters of an inch in diameter, two inches above the aortic valve. The aorta was dotted with patches of yellow atheroma in an early stage. The valves were healthy. The myocardium and the visceral pericardium in general were healthy with a fair deposit of fat. In front of the apex of the left ventricle, however, in an area about three-quarters of an inch in diameter the pericardium presented a nodular, yellowish-gray gelatinous surface, beneath which, on section, the myocardium was found to be replaced by a soft, yellowish-gray gelatinous tissue, with here and there soft, yellowish nodules, which appeared about to break down. This was situated at the base of one of the papillary muscles, and on microscopical examination proved to be a gumma. There was no local dilatation of the ventricular wall. An early gumma was found in the pancreas, about half an inch in diameter. Otherwise the necropsy was negative.

A Case of General Paralysis of the Insane in Early Life.—In *The Lancet* of September 23, 1899, Dr. Mair reports the case of a girl fourteen years old, who had suffered from mental derangement for four years. The mother and paternal grandmother had died in asylums. The patient had been healthy until the age of six years, when she became restless and destructive in her habits, tearing off her clothes and putting them into the fire. She also wandered about the street, and gradually became so mindless that when she was ten years old she was sent to an institution for imbeciles. At the age of twelve she was unable to recognize her friends, was dirty in her habits, and quite unfit to do anything for herself. When she came under observation, she was hardly able to walk Her gait was spastic, and the deep and superficial reflexes were equal and exaggerated. There was apparently no change in general sensibility. The pupils were dilated and unequal, the right being larger than the left. Both responded in accommodation, but sluggishly to light. Fibrillary tremor of the face was present, but the state of the tongue could not be ascertained. The movements of the hands and feet were at times irregular and tumultuous. The abdomen was somewhat retracted. Beyond the short, sharp, so-called hydrocephalic cry, the patient uttered no sound. She gave no sign of any intelligence, and was dirty in her habits. The face was pallid and anæmic. A mass of swollen glands, hard and isolated, was present in the axilla. The other organs of the body were apparently normal. The urine was pale and of low specific gravity, but presented no other feature of importance The temperature was subnormal and continued so until a few days before death, when it became febrile. The patient was compelled to go to bed on account of difficulty in walking. The muscles of the lower extremities were in a state of clonic spasm, but ultimately this state passed into tonic spasm, so that the thigh was retracted on the abdomen and the legs were flexed on the thigh. The choreic movements increased in extent and in amount, but affected chiefly the upper extremities and the face. The deep reflexes disappeared, but the exaggerated superficial reflexes remained. The patient grew more and more emaciated and failed progressively till death ensued. On post-mortem examination the head was found to be nineteen inches in circumference, narrow in front, but wide in the middle parietal region. The sutures of the calvarium were well marked. The skull cap was light and porous, the diploe increased. The frontal bone was three-eighths of an inch, and the occipital one-quarter of an inch thick. The dura mater was thickened. In the subdural space false membranes consisting of fibrin, covered the whole of the upper surface of the hemispheres. This fibrinous deposit was in its thickest parts a quarter of an inch in thickness. It tapered to one-eighth of an inch at the circumference of the brain. The pia mater was thickened and presented milky patches, especially in the region of the cerebral veins. A gelatinous deposit filled the sulci. Clear serous fluid was present in some quantity in the spaces of the meninges and ventricular cavities. The convolutions were fairly well marked. The brain weighed twenty-four ounces. Microscopical examination disclosed marked thickening of the pia mater and infiltration of leucocytes. There

was marked subpial felting. The blood-vessels presented hyaline changes, marked periarteritis, and extravasation of blood-corpuscles. The neuroglia cells were proliferating, and the neuroglia fibres, increased in density and number, caused extensive fibrosis. The nerve cells were much disintegrated.

**The Etiology and Treatment of Aortic Aneurism.**—In the *Berliner klinische Wochenschrift*, No. 12, 1899, Dr. Aaron expresses the opinion that in the majority of cases aneurism of the aorta is of syphilitic origin, the history of infection being often either suppressed or overlooked. This would seem to be particularly true when the vascular disease appears early in life, and especially if no other etiological factor has been operative. In every event the patient should have the benefit of any doubt, and anti-syphilitic treatment should be instituted as promptly as possible. In this connection skiagraphy may be of service in arriving at an early diagnosis. The administration of iodides in effective doses is not likely to be harmful, even if the condition is not syphilitic, while if there is the slightest possibility of such an origin mercurial inunctions should in addition be practised faithfully.

**The Elimination of Uric Acid in the Urine of Gouty Patients.**—As the outcome of an elaborate clinical investigation His (*Deutsches Archiv fur klinische Medicin*, Nos. 1 and 2, vol. 65, 1899) has reached the following conclusions: (1) The mean daily elimination of uric acid in gouty patients does not differ from that in healthy individuals. (2) The daily elimination of uric acid is subject to considerable and inexplicable variations in both healthy persons and gouty patients. For this reason the estimations of individual days or for short periods are inadequate for a decision. (3) The acute attack of gout is inaugurated with a diminution in the elimination of uric acid, which precedes the attack by from one to three days. The attack is followed by an increase in elimination, which reaches its maximum between the first and the fifth day. (4) The mean daily elimination of uric acid in gouty patients both during the attack and in the intervals between attacks exhibits no typical variation. (5) Sodium bicarbonate and various mineral waters, as well as the use of lemon juice, do not appreciably influence the amount of uric acid excreted. (6) Lithium carbonate appears constantly to diminish the elimination of uric acid slightly.

**Mercury in Diseases of the Heart.**—Wallace Beatty (*The Dublin Journal of Medical Science*, October) makes the following statements regarding the cases in which mercury is of real value: (1) Of all conditions in which mercury is useful, one in which it is most certain to do good is general venous engorgement due to chronic primary mitral-valve disease. In a typical case there are a rapid, irregular, compressible pulse, physical signs of dilatation of heart, a regurgitant or obstructive murmur, full and pulsating cervical veins, an enlarged and congested liver, high-colored, scant, and albuminous urine from congested kidneys, anasarca, and perhaps some ascites—in short, all the evidences of back pressure. (2) The cases of general venous engorgement dependent upon mitral incompetence (relative incompetence) secondary to aortic regurgitation of old standing. (3) Cases of dilatation of the heart with general dropsy, but yet no obvious valvular disease, there being no murmur and no evidence of kidney disease. (4) Cases of general venous engorgement from failure of the right heart, caused by severe emphysema and bronchitis. (5) Cases of general venous engorgement due to cardiac dilatation following upon long-continued hypertrophy of the left ventricle, due to chronic interstitial nephritis.

**Sterilization of the Hands.**—As the result of personal experiments and from a consideration of those of others, Freeman (*Annals of Surgery*, October, 1899) submits the following propositions: (1) None of the methods of sterilizing the hands thus far suggested can be absolutely depended upon. Many positive results are arrived at by means of faulty experimental technique, the culture media becoming impregnated with antiseptics, the skin temporarily hardened by alcohol, formalin, etc., or the hands not being subjected to sufficient maceration and friction in the culture medium. (2) Under circumstances amid which it seems desirable to do so, much may be accomplished by sweating the hands in a hot-air oven, by wearing rubber gloves for some time prior to an operation, or by immersing the gloved hand in hot water. Mere prolonged soaking in very hot water, although not so effective as dry hot air, must have some favorable effect. It is difficult to understand, however, how the sweating method can dispose of all the micro-organisms beneath the nails. The procedure will hardly be employed extensively, owing to its inconvenience. (3) Excessive brushing beneath the nails, as much even as the sensitive tissues will tolerate, seems merely to stir up the bacteria when carried beyond a certain point. Little is to be hoped for from this means. (4) Thus far, the only really reliable means of rendering the hands aseptic is to encase them in sterilized rubber gloves, but if the gloves become torn, as they often do, the danger of infection is considerable, owing to the bacteria that have accumulated beneath from perspiration. Coating the hands with various substances has been tried and found ineffectual. Cotton gloves, although they soon become contaminated by exudations from the skin, probably do some good, especially if changed frequently, by filtering out the bacteria, as it were, and preventing their entrance into wounds.

**The Relationship between Syphilis and General Paralysis of the Insane.**—Campbell (*British Medical Journal*, September 16, 1899) indicates as follows some of the grounds upon which is based the assumption that there is an intimate relationship between tabes dorsalis and general paralysis on the one hand, and syphilis on the other: In the first place, statistical enumerations prove that in a large proportion of cases an attack of syphilis has preceded the onset of general paralysis. In the next place it appears that the majority of cases of general paralysis emanate from localities where the traffic in immorality is greatest, and for this reason it is a disease of urban and industrial communities rather than of rural populations. Thirdly, the more the etiology of juvenile or adolescent general paralysis is studied, the more clear does it become that the majority, if not all, cases arise in the victims of hereditary syphilis. Another argument in favor of the syphilitic origin of general paralysis is the occurrence of that disease in married couples who have infected one another with syphilis. The fifth indication in favor of the syphilitic origin of general paralysis is the occasional occurrence of syphilis in parent and offspring. In the next place, no case has been recorded of a general paralytic acquiring syphilis after the mental symptoms have declared themselves, in spite of the fact that many of the patients, at any rate at the commencement of their illness, are prone to sexual excess, and are, therefore, liable to expose themselves to contagion. Lastly, the influence of social conditions on the prevalence of general paralysis is of importance. It is stated that among the officers of the Continental armies general paralysis is common, but among members of the priesthood it is rare, and among women of high standing it is practically unknown.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

New York, November 4, 1899.

## THE WAR IN SOUTH AFRICA AND THE BRITISH ARMY MEDICAL SERVICE

To judge from the present condition of affairs in South Africa, there would seem to be but little doubt that, contrary to the opinion of many military experts based on the successes gained by the British in the first engagements, the Boer war will be a protracted and sanguinary struggle. Especially should it be remarkable for the wounds inflicted by the modern small-bore bullet, owing to the superb marksmanship of the Boers. Consequently the lessons to be learned from a surgical standpoint will assuredly be of the very greatest importance. At the same time the war will be an extremely severe test of the efficiency of the British army medical service—the first, indeed, since the Crimean war—and the manner in which its members acquit themselves will be watched with almost as much interest in this country as in Great Britain itself.

We ourselves have been of late acquiring by bitter experience the knowledge that when war is undertaken no department of the army needs such careful supervision as that of the medical, and that if this is not done the suffering entailed will be awful to contemplate. Grave charges have been made from many quarters against the manner in which the British army medical department is conducted. The contention has been advanced times without number that the supply of surgeons to the British army in times of peace is inadequate, and woefully so, to meet any pressing emergency, and in addition to this that many of its surgeons are, from lack of proper training and experience, not fitted to cope with the difficulties placed upon them by war on a large scale.

That everything in this respect is not as it should be, is a fact too patent to be evaded by those who have followed the discussions on the matter in the medical and lay press of Great Britain, as well as evidenced by the widespread dissatisfaction with the existing order of things exhibited by the British army surgeon himself, and by the difficulty experienced in inducing the best class of young medical men to join the army. Dr. Alexander Ogston, the distinguished Scotch professor and authority on army surgery, contributed a paper at the recent meeting of the British Medical Association in which he voiced the opinion of those who believe that radical reforms are indicated in the conduct of the British army medical service. His remarks were strongly traversed by some, and no doubt, like so many ardent reformers, he may have taken a somewhat too pessimistic view of the case and exaggerated the defects of the present system, yet it is to be feared that the greater part of the English medical profession are quite conscious that his strictures were more or less warranted by facts. The professor in no way denies that the British army medical service fulfils its duties efficiently under ordinary conditions, probably in a better manner than could be achieved by any other country, but he asserts that it must not be inferred from this that it is in a state to deal with a war against a great power in which large numbers of wounded must fall to be treated. What ever may be the condition of efficiency of the British army medical department, one fact at least has already been made very clear, that is, as regards its inadequacy. As stated in the MEDICAL RECORD of October 21st, the authorities, in order to make up the British army medical service for the one army corps for South Africa to fighting strength, have been compelled to employ a number of contract civil practitioners.

It is said that the British war office is wholly to blame for this unpleasant situation. For many years it is stated there has been constant friction between the army medical authorities and the war office. Some slight changes have been effected and concessions made within the past few years, but until radical and satisfactory reforms have been introduced it will be—according to those in a position to speak from actual knowledge—impossible to place the British army medical service on a sound basis.

Army authorities are too much given to the habit of taking for granted that surgeons can be obtained at any time, and do not sufficiently consider that the training of an army surgeon is just as important as that of the army officer. However, it is to be hoped that the condition of the British army medical department is not nearly so black as it has been painted, and that, contrary to adverse prognostications, it will pass the ordeal in South Africa scathless.

## MORPHINISM, DRINK, AND THE MEDICAL PROFESSION.

ARE physicians more addicted to the morphine habit and to strong drink than members of the other learned professions? Unfortunately it would appear, if statistics may be believed, that the answer to the question must be in the affirmative. Dr. T. D. Crothers at the recent meeting of the New York State Medical Association, averred that after an extended study of the subject, and the collection of statistics, the estimate had been made that ten per cent. of all medical men used morphine. In a work on the morphine habit, published in Paris in 1897, the whole question is threshed out in a fairly exhaustive manner.

Statistics are furnished of one thousand cases collected from all parts of the world showing that of the

male morphinists the medical profession supplies the largest number, forty per cent. According to official statistics collected in 1898 with regard to the prevalence of the morphine habit in Prussia, it appears that of ninety-two male victims of the habit under treatment in institutions in Prussia in the year 1895, nearly one-third belong to the medical profession. The estimate brought forward by Dr. Crothers, that of all medical men ten per cent. were given to the use of morphine, would seem to be somewhat misleading, for the fact must be taken into account that in some countries the drug is not taken to any great extent. In Great Britain, for instance, probably not more than one or two per cent. of the medical men are addicted to the habit, while in France, Germany, and this country the practice is much more prevalent. However, if an average is struck, the estimate supplied by Dr. Crothers may be found more or less accurate.

With regard to the charge brought against physicians of indulging too freely in strong drink, here again it is question to a great extent of locality. In this country medical men do not fly to alcohol to stimulate their jaded nerves to the same degree as is the custom in many other lands. Strong drink is much more freely used for this purpose in Great Britain, Denmark, and Russia among physicians than here. Nevertheless the main point cannot be evaded, viz., that physicians are more addicted to the use of morphine and alcohol than other professional men. This being so, what is the cause? for no one can pretend to assert that the physician is naturally more vicious than his fellow-man, probably the reverse. Are there no extenuating circumstances? If the matter be well looked into, it will quickly be seen clearly enough that there is greater temptation for the doctor to use morphine or a drug of a like nature or alcohol than for a man in any other branch of life. The chief factor is undoubtedly the mental and physical strain forced upon him by the exigences of his profession. The fact must be remembered that the busy doctor is at the beck and call of every one; he has not a moment he can call his own. Often at night, after a heavy day's work, when the minister or lawyer is enjoying the sleep of the just, an urgent message will be sent in, and go he must, maybe to a case involving life or death and requiring the exercise of his utmost skill and intelligence. After such tension of mind and body a reaction will surely supervene. What cause can there be for wonder, then, that the temptation to stimulate or soothe exhausted nature and the tired nerves by means of alcohol or drugs proves too great, and he falls a victim? Again, take, for example, a physician practising in the country in a sparsely populated district, driving long distances by night and day, exposed to all inclemencies of the weather, is there not greater excuse for a man circumstanced thus to resort to a means which will, for a time at least, infuse fresh life and vigor into his body and mind than for him whose pursuits call for no such exertion? Sick people, too are notoriously selfish, and have no consideration for the physician, but expect, however trivial may be their ailments, that when he is sent for he will go promptly; if he does not, in very many instances they will dispense with his services entirely. The medical man is well aware of this idiosyncrasy on the part of his patient, and when fagged out or racked with pain will turn to the baleful drug or the only less harmful alcohol in order to be able to fulfil his engagement.

In speaking in this strain it must be distinctly understood that there is no intention to condone the sin or to palliate the folly of using either drug or spirit in the manner referred to, but we would merely point out that in many instances the long-suffering doctor who has become a victim of the habit should be regarded as an object for pity rather than blame, and would further emphasize our contention that medical men are more exposed to temptation in this respect than are members of other professions. The truth is beyond controversy that the use of morphine, continued as a habit, will lead—and in some cases much more quickly than in others—to mental, moral, and physical destruction, and we would advise in the strongest possible terms that medical men, whatever may be their trials, strictly guard themselves against seeking a panacea in morphine. Once the needle has been inserted and the insidious drug injected into the system, allaying pain, composing the tired nerves, and, for a time, bathing the mind in the waters of Lethe, it will again and again be resorted to for the same purpose, until at length, sometimes gradually, sometimes more rapidly, it will complete the ruin of its slave. Totally to abjure its use is the surest safeguard against this result.

## AN UNPARDONABLE INDIGNITY.

Few greater outrages have been committed upon medical men in New York than the arbitrary arrest last week of two reputable physicians, Drs. Purdy and Maier, who had been called to a charity case, seeing it but once, and who subsequently recommended that the patient, who was a poor woman, should be taken to Bellevue Hospital, where she died a few days later. An autopsy was held, about the results of which there seems to have been some justifiable difference of opinion, and the matter was left to the police for "investigation," it being alleged that the cause of death was criminal abortion. The patient had during life presented the symptoms of acute articular rheumatism and endocarditis, and the existence of pelvic symptoms was not even recognized or suspected by the doctors or by the visiting staff of Bellevue, or, in fact, any one else except the astute coroner's physician. The "investigation" of the police captain consisted in finding out the names of the physicians who had last seen the patient, and after being pilloried in the yellow journals, and subsequently spending a morning in the coroner's court, they were "exonerated" by the coroner and the jury; and will for some time suffer from the stigma of a false arrest in a questionable case.

If this sort of thing is allowed to go on, any doctor may be dragged to a police station at the pleasure of any autocratic coroner or any over-zealous and notoriety-seeking police captain.

## SPORADIC LEPROSY.

If the kindly hearted officials who placed a row-boat within easy reach of the few detained lepers on North Brother Island a couple of years ago thought they had solved the problem of how to care for our lepers, they must since then have realized the inadequacy of their method. Last month one of those who had escaped died in an isolated hut on Blackwell's Island, where it had been found necessary to take him. A second is said to be now occupying the place vacated by his presumably more fortunate companion.

A third, according to a newspaper account, after keeping a gambling-room, losing his capital, and being deserted by his white wife, lived for a time with his cousin, a laundryman, where the police found him bound to the floor with bamboo stakes lacerating his flesh. His fellow-countrymen were chanting about him, it is said, in an attempt to drive out the devils which they thought possessed him. He was removed to a bare top-floor room in Chinatown, known as the "morgue," where, at last accounts, he was reported to be dying. Sing Jug, who died on the island, is said to have contracted the disease in San Francisco.

Just now San Francisco is having troubles of her own growing out of this unsettled problem. The local authorities desire the government to transport one of their residents, a woman with advanced leprosy, to the leper colony which is now ours in Hawaii. The lady objects. The Secretary of War has been unable to reach a decision. In the Record of November 7, 1896, we asked what had become of the strong and urgent resolutions adopted over a year before by the American Dermatological Association, when it met in Washington and devoted a day to the leper question?

The answer has this year been received in a public document approved March 2d, and entitled "An Act for the Investigation of Leprosy":

"Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the Supervising Surgeon-General of the Marine-Hospital Service, under the direction of the Secretary of the Treasury, shall appoint a commission of medical officers of the Marine-Hospital Service to investigate the origin and prevalence of leprosy in the United States, and to report upon what legislation is necessary for the prevention of the spread of this disease; the expenses of this investigation, not exceding the sum of five thousand dollars, to be paid from the fund for preventing the spread of epidemic diseases."

Baltimore has just been relieved by death of a leper woman, Mary Sansoni, who has given the city and hospital authorities considerable trouble in one way and another for many years. When the patient was a young girl, she went to Demerara, British Guiana, and remained for several years, undoubtedly contracting the disease from one of its many subjects in that region. She had come to Baltimore from Allegheny, and refused to return, while Allegheny refused to have her do so. Property-owners secured an injunction against her stay in some old quarantine quarters, so the Johns Hopkins people opened their doors, and there she died.

Death settles the problem for a day. Will the gentlemen of the Marine-Hospital service please get together, do five thousand dollars' worth of investigating, and tell the lawmakers what is required in the premises?

There are plenty of other lepers in this city and elsewhere who are rapidly approaching the point of intolerableness, which causes citizens and city fathers to act in a most uncharitable manner toward these unfortunates. We have repeatedly pointed out means of preventing the spread of the disease on humane and kindly lines. Of course, since the New York board of health pronounced leprosy not contagious, no attempt has been made to seek the remedy in enforced isolation, although, to be sure, the lepra conference recently held in Berlin decided that it was contagious, and declared that isolation was the only remedy. One question for the Marine-Hospital commission to settle will be whether we are to go by the board or by Berlin; whether we are to abide by a home-made decision or one made in Germany, but participated in by the profoundest thinkers in these matters, drawn from all quarters of the globe.

## News of the Week.

**Smallpox** is reported to prevail to an alarming extent in many parts of Texas, and fears are felt of an epidemic spreading this winter unless the State board of health adopts very stringent precautionary measures.

**Monument to an Army Nurse.**—A monument erected by the Daughters of the American Revolution to the memory of Reubena Hyde Walworth, who died of disease contracted while nursing soldiers at Montauk Point a year ago, was unveiled and dedicated in Greenridge Cemetery, Saratoga, on October 18th.

**A Hospital in Cuba Destroyed.**—It is reported that a hospital at Sagua la Grande, Cuba, was destroyed by a tornado on Friday of last week, four of the patients being killed. The hospital was built by the American authorities.

**Unsanitary Conditions at Fort Meade.**—In the annual report of Brig.-Gen. James F. Wade, commanding the department of Dakota, recently made public, it is stated that the three posts and one camp occupied are in very fair condition, with the exception of Fort Meade, which is unsanitary and has reached a point where it is a question of reconstruction or abandonment.

**Doctors in Politics.**—Three well-known physicians of this city are candidates for election to the State Assembly, all of them on the anti-Tammany side. Dr. Nelson H. Henry was elected to the Assembly from the Fifth District last year and is a candidate for re-election. He is a graduate of the College of Physi-

cians and Surgeons in 1879 Dr. Samuel F. Brothers was nominated in the Fourth District by the Citizens' Union, and has been indorsed by the Republicans. He is a graduate of the College of Physicians and Surgeons in 1890. Dr. John Franklin Southmayd, a graduate of the College of Physicians and Surgeons in 1892, is the Republican candidate in the Twenty-sixth District.

**A Medical Meeting Forbidden.**—A congress of railway surgeons, which was to have met in Warsaw on October 20th, has been indefinitely postponed by the Russian minister of railways.

**To Abolish the Side-Saddle.**—It is announced from Cleveland that the Health Protection Association, a local body of sanitary betterers, is about to inaugurate a crusade against the present mode of horseback riding for women. It is asserted that the side-saddle is dangerous, and that a woman should wear divided skirts and bestride the horse man fashion. High hats, corsets, and trailing skirts are also subjects of attack by this association.

**The Guild of St. Luke.**—The annual service in St. Paul's Cathedral, organized by the Guild of St. Luke the Evangelist and Physician, to emphasize the working together of the two professions of religion and medicine for the good of humanity, was held on Thursday evening, October 19th. The bishop of Stepney preached the annual sermon.

**The Medical and Chirurgical Faculty,** which is the State society of Maryland, will hold its semi-annual meeting at Westminster on November 14th. At this meeting the principal points of interest will be the addresses of Dr Flexner, now of the University of Pennsylvania, and of Dr. Barker, of the Johns Hopkins University. These speakers will relate their experience in Manila and give some account of tropical diseases prevalent there. In addition to this Dr. Barker, who visited some of the plague-stricken districts in China, will add something on that subject.

**Laboratory Committee of the American Public Health Association.**—The programme of papers to be presented by this committee at the meeting of the Public Health Association in Minneapolis on October 30th, has been published. The following subjects have been selected for discussion with special reference to co-operative work by the laboratory committee: I. Disinfection; II. Shortening the period of infectiousness in contagious diseases; III Disposal of sewage and waste; IV. Milk and infection by milk; V. Transmission of specimens to laboratory. In addition twenty-one titles of papers on general subjects have been sent to the secretary.

**Restaurants in Cemeteries.**—Last summer the health authorities in the Borough of Brooklyn had some contention with the owners of a cemetery who persisted in renting a building within the cemetery grounds for use as a restaurant and drinking-saloon. In order to prevent any similar misunderstanding in the future, the board of health has now amended section 171 of the Sanitary Code, relating to cemeteries, by adding the following clause: "No food or beverage or other article of human consumption, may be sold, exposed, or offered for sale, within any premises used as a cemetery, in the limits of Greater New York."

**The Famine in India.**—It is feared in India that the present famine will affect a larger area than that of 1896. It is likely to be most severe in the vast tracts of western India.

**Work of the Pasteur Institute in Rome.**—In the recent published report of the Antirabic Institute in Rome, statistics are given of the results of the inoculation treatment since the establishment of the institute. From June 1, 1895, to May 1, 1899, six hundred and thirty persons were treated, of whom ten died, giving a mortality of 0.16 per cent. One hundred and sixty six persons were treated in 1896, with two deaths. In both the fatal cases the patients were children who had been severely bitten in a number of places, and who were brought to the institute sixteen days after. In 1897, of two hundred and twelve cases treated, death occurred in one; in this case, also, the bites were multiple and deep; the disease developed on the nineteenth day of treatment. In 1898, of one hundred and seventy-one patients treated, three died, all during the treatment or within fifteen days of its completion.

**Philadelphia Neurological Society.**—At a stated meeting, held October 23d, Dr. Charles S. Potts exhibited two brothers, about ten and twelve years old respectively, suffering from progressive muscular dystrophy of pseudo-hypertrophic type; and also a man presenting a combination of paraplegia of organic spinal origin and hysteria following severe railway injury. Dr. D. J. McCarthy reported a case of ambulatory automatism, probably of epileptic nature, occurring in a boy of sixteen, with a history of convulsive seizures early in life, who had attacks attended with loss of consciousness and purposive and well-co-ordinated motor manifestations. Dr. F. X. Dercum presented a communication upon a case of hemiplegia, jargon aphasia, hemianopsia, and neuritic pain in the arm of the paralyzed side. He was disposed to consider the lesion as vascular occlusion, probably embolic. Dr. Dercum also recorded a case of acute anterior poliomyelitis with paralysis of all four extremities, occurring in a child, in which lumbar puncture disclosed the presence of the diplococcus of pneumonia in the cerebro-spinal fluid. Dr. Joseph Sailer reported a case of sensory equivalent for the epileptic attack, occurring in a young man, with a previous history of convulsive seizures, who was on several occasions seized with headache, numbness, and tingling on one side of the body, and derangement of vision. Dr. S. M. Hamill reported a case of migraine with aphasia and numbness in one arm, and also with visual hallucinations. Dr. William G. Spiller reported two cases of partial sensory epilepsy, in which after a long history of attacks of migraine convulsive seizures appeared. The analogy between epilepsy and migraine was especially emphasized.

**A Testimonial to Dr. E. Eliot Harris.**—A fitting close to the exceptionally large and successful annual meeting of the New York State Medical Association was the presentation to the chairman of its committee on legislation, Dr. E. Eliot Harris, of a testimonial in recognition of his indefatigable labors and peculiarly valuable services, during the past year, in matters of legislation, notably that designed to check the dispensary abuse. Almost immediately after the dispensary bill had become a law, certain members of the profession, who were most familiar with the details of the work that had been done during the session of the legislature, set on foot a plan by which the medical profession could give evidence, in a substantial way, of its appreciation of what had been so well and so unselfishly done. As a result, there was a quiet gathering in the Mott Memorial Hall on Friday evening, October 27th, of those most interested. Dr. Harris had been beguiled into coming, though completely ignorant of the pleasant surprise in store for him. After he had been presented with a handsome silver tea service, and several appropriate speeches had been made, the evening was given over to social enjoyment and the narration of anecdotes drawn from the experience of the last legislative campaign.

**Philadelphia County Medical Society.** — At a stated meeting held October 11th, Dr. J. M. Anders read a paper entitled, "Gall-stone Crepitus and Friction, with Illustrative Cases," in which he dwelt upon the diagnostic utility of these two phenomena, laying especial stress upon a combination of palpation and percussion in the examination—auscultatory palpation. Dr. E. Laplace read the "Report of a Case of Acute Purulent Peritonitis, Accompanying Appendicitis, Treated by a New Method." The prognosis appearing fatal, after the abdomen was opened and the adhesions were freed, combined permanent irrigation and drainage of the peritoneal cavity were established and continued uninterruptedly for seventy-two hours with physiological saline solution at a temperature of 100° F., some three hundred and sixty pints in all being used. The patient survived. Dr. B. F. Stahl demonstrated a man presenting a "musical heart."

**Philadelphia Pediatric Society.**—At a stated meeting held October 10th, Dr. F. A. Packard exhibited a colored child, four years old, presenting symptoms of both scurvy and rickets. Dr. Packard also demonstrated cerebro-spinal fluid obtained by lumbar puncture from a case of traumatic meningitis, and which, though apparently clear, was found on closer inspection to contain fine floating flocculi. Dr. J. H. McKee exhibited a child, one year old, presenting marked symptoms of rickets, in which the history pointed to the previous existence of scurvy. Dr. L. C. Peter exhibited a case of peripheral facial palsy in a boy, aged about ten years, complicated by herpes zoster in the distribution of the affected nerve. Dr. J. F. Schamberg presented a communication detailing the results of "A Clinical Study of the Lymphatic Glands in One Hundred Cases of Scarlet Fever." Widespread glandular enlargement of varying degree was observed in most of the cases, the inguinal glands exhibiting changes in all. The exanthem must be looked upon as a dermatitis dependent upon toxic influences, and to which the glandular involvement may stand in direct relation. Similar adenopathy may attend other exanthemata. The degree and extent of desquamation will depend upon the intensity of the cutaneous inflammation. Dr. H. A. Marcy, Jr., read a paper entitled "Auto-intoxication as a Cause of Cyclic Vomiting," in which he reported three cases, two of which terminated fatally. In one of the latter a post-mortem examination disclosed necrosis of the membrane of the gastro-intestinal tract with degenerative changes in the parenchymatous viscera. Hypodermic injection of morphine and atropine have proved highly serviceable in the treatment of attacks, and intravenous infusion of saline solution was suggested as a promising measure.

**Give Your Address.**—Dr. Andrew H. Smith writes: "If writers for medical journals would always append their addresses to their contributions, they would receive many more acknowledgments from the busy men to whom they forward their reprints."

**Typhoid Inoculations** have been tried on a large scale in the case of many of the British troops sent to South Africa. This was not made compulsory, but the company commanders were instructed to urge the men to allow themselves to be inoculated, and most of them submitted to the experiment.

**The New York Obstetrical Society.** — At the annual meeting of the New York Obstetrical Society, held on October 10th, the following officers were elected: *President*, Dr. Clement Cleveland; *First Vice-President*, Dr. H. J. Boldt; *Second Vice-President*, Dr. R. Waldo; *Recording Secretary*, Dr. R. L. Dickinson; *Assistant Secretary*, Dr. E. A. Tucker, *Corresponding Secretary*, Dr. E. E. Tull; *Treasurer*, Dr. J. Lee Morrill.

**The Smoke Nuisance.**—There is an encouraging prospect that the soft-coal danger which has for some time been menacing this fair city will be met and removed. The board of health, as we noted last week, has secured the conviction and punishment of certain offenders. The Merchants' Association and other influential bodies are actively furthering the work of the health board, and the United States government officials are moving against the burning of soft coal by tugs and other vessels in the harbor. Complaints of the burning of soft coal by the tugs and lighters of the New York Central Railroad Company and by its freight locomotives having been made, President Callaway of that company promptly gave instructions that such use should cease. In a recent letter, the president of the Merchants' Association said that "this movement is one which is bound to resolve itself into action before the legislature looking toward the absolute prohibition of the use of soft coal in this city, and in making the penalty for its use far more severe than it is now. Complaints have been numerous in many directions, especially against factories in the city, and

the board of health is determined to put an end to this nuisance. New York should be the most attractive city in the country, and the saving in cost attendant upon the use of soft coal is not sufficient to warrant destroying the city's chances in that direction."

"The Lancet" is seventy-six years old, the first number having been issued on Sunday, October 5, 1823.

**The Plague** seems to be definitely established at Quero, near Toledo, in Spain, and at Santos in Brazil, two or three new cases being reported in each place daily. Eleven cases are now under treatment at Santos, and five deaths have occurred since October 17th.

**The Druggists' League** of this city, which endeavored last year to secure the passage of a bill by the legislature regulating the hours of labors for drug clerks, has entered the political arena this year in the hope of defeating the re-election of the opponents of that measure.

**Yellow Fever** is practically epidemic at Jackson, Miss., though there as elsewhere in the South the disease exists in mild form. A case has occurred in the penitentiary. There are also a few cases at Flora, a town about twenty miles from Jackson. A man who arrived here ill with yellow fever on a steamer from Cuba died a few days ago at quarantine. There were no other cases on the vessel.

**Western Surgical and Gynæcological Association.**—The ninth annual meeting of this association will be held at Des Moines, Iowa, December 27 and 28, 1899. Titles of papers should be sent to the secretary, Dr. George H. Simmons, 61 Market Street, Chicago, as soon as convenient, but not later than November 20th, to insure a place on the programme. The president of the association is Dr. H. C. Crowell of Kansas City, Mo.

**Prize of the Massachusetts Association of the Boards of Health.**—A prize of $50 is offered by this association for the best essay on "What shall boards of health do officially with persons who are carrying diphtheria bacilli in their throats or noses, without being ill, to prevent the spread of the disease, and how can these bacilli be most rapidly destroyed?" The essays, which must be typewritten and accompanied by the author's name in a sealed envelope, should be sent before January 15, 1900, to Dr. Henry P. Walcott, 141 State House, Boston, Mass.

**Congresses to be Held in Paris in 1900.**—Announcement is made of over one hundred international congresses which are to be held in Paris during the exposition. A special building is to be erected for the convenience of these assemblies. This building will be about six hundred and fifty by three hundred feet in ground area and some seventy feet in height. The ground floor will contain the exhibits of social economy, and above will be several large halls for the congress talks. It is difficult to think of any question of public or even private interest which will not be open to discussion in one or other of these congresses. Among the subjects of more or less interest to physicians are medicine, medical deontology, homœopathy, dermatology and syphilography, alcoholism, abuse of tobacco, insurance, charities, electricity, botany, chemistry, the blind, deaf-mutes, hygiene, hypnotism, pharmacy, the medical press, psychology, and anthropology.

**Opposition to a New Dispensary.**—A hearing took place last week before Dr. Stephen Smith of the State board of charities, as to whether the board should approve of a charter granted to the Emanuel Hospital and Dispensary, which it is proposed to establish in East Broadway. The reasons given for the establishment of the hospital were that the population of the district was very dense, and that the only other hospital within reach, besides the Gouverneur Hospital, was the Beth Israel Hospital, that had twenty-eight beds. To start the hospital, the papers stated, $40,000 had already been pledged and was available, and as soon as it is started a further amount of $60,000 had been promised. The opponents of the new institution alleged that it was not a charity, but was a business venture of certain physicians and others. They maintained, also, that there was no need of any more medical charities in the lower east side of Manhattan, for there were already existing hospitals and dispensaries with sufficient accommodation, and in addition to this nearly all the inhabitants of the district belonged to lodges and other associations providing medical attendance for their members. No decision was reached, and the hearing was adjourned.

**Medical Matters in the Transvaal War.**—Sir William MacCormac, president of the Royal College of Surgeons, has volunteered for service in the medical department of the British army in South Africa. His position will be that of consulting surgeon with the forces of Gen. Sir Redvers Buller.—In reply to a question in Parliament last week relative to the arrangements made for the care of the wounded in South Africa, Mr. Wyndham, the parliamentary secretary for the War Office, said there were ample stocks of medicines, etc., with all the British forces; but possibly, if the British hospital corps was forced to care for many Boers, the resources would be strained. The government was making provision for that contingency.—The imperial authorities have granted permission for trained nurses and surgeons to be sent from Canada with the Colonial troops, but in view of the demands made upon the space available in the transport *Sardinian*, which has sailed to convey the Canadian volunteers to Cape Town, accommodation could not be found for many extra physicians or nurses.—In a despatch to *The Sun* regarding the Boer medical service it is stated that the Transvaal has the Red Cross society and an efficient St. John's ambulance society as auxiliaries to the regular military medical corps. The latter is well equipped, but is perhaps numerically too weak. It was mobilized before the burghers were called to arms. When the war commenced several railroad trains were made ready fitted with swing beds and all modern conveniences for alleviating suf-

fering. A field hospital was attached to every commando and the hospital headquarters fixed at Pretoria, to which place all the burghers wounded within reach of the railway will be sent with the least possible delay. The women of Pretoria and Johannesburg responded numerously to the invitation to do volunteer duty in nursing, "for the sake of their Lord and their country," as the appeal read. A. H. Bleksey, chief representative in the Transvaal for St. John's Ambulance Society, with Drs. Croghan, Lillpopp, and Mangold, organized classes, and lessons in nursing and first aid to the wounded and other useful instruction were given. Several hundred women attended the classes. As soon as a sufficient number had been trained, the English nurses were turned out of the Johannesburg hospitals, Dr. Mangold asserting that none but Dutch women were fit to nurse the Dutch. —A number of American women residing in London have undertaken to raise £30,000 within two weeks for the purpose of equipping a hospital ship which will be sent to South Africa. The British government has turned over to them the *Maine*, which the Atlantic Transport Line presented for the purpose, and the American women will equip the *Maine* with a complete medical outfit. A firm of manufacturing chemists will give all the medicines and drugs. The ship will accommodate two hundred patients, and will have a staff of four doctors, five nurses, and forty non-commissioned officers and orderlies.

**Bequests to Hospitals.**—According to the will of the late Cornelius Vanderbilt, St. Luke's Hospital in this city will receive $50,000, and the Newport (R. I.) Hospital $10,000. Yale University will receive $100,000.

**Burning of a Hospital.**—The City Home and Hospital, in Findlay, Ohio, was destroyed by fire on October 23d. The fire was caused by the crossing of two electric wires. The patients were removed, the last being taken out but a moment before the walls fell. Seven of them are, however, in a precarious condition from the exposure and excitement.

**"The American Medical Quarterly"** is the name of a new publication, the second number of which, bearing date of September, 1899, is before us. The editor is Dr. William Warren Potter, which fact in itself is a sufficient guarantee of excellence. The contributors to this number are Drs. A. Jacobi, Joseph Price, F. R. Sturgis, Edward Brush, Adam Wright, Mathew D. Mann, and Nelson W. Wilson. There is a very good portrait of Dr. Joseph D. Bryant, recently president of the New York State Medical Association.

**The Exhibit of the Johns Hopkins University,** including that of the Medical School, for the Paris Exposition, is now being prepared by the librarian of the university, and will be forwarded in December. This collection will form a part of the educational exhibit of the United States. Articles relating to the scientific publications of the university will be sent, also to work in the physical laboratory, in geology, and in the biological sciences, especially in anatomy, physiology, and pathology. The exhibit of the Medical School will be included in this last division. It will consist of plates illustrating the work done in the laboratory courses, and of publications reporting the original investigations which are being carried on under the auspices of the Medical School. There will probably be examples of the laboratory work of the students.

**The Baltimore Hospital for Consumptives.**—Improvements are to be made in the Hospital for Consumptives of Baltimore. An addition to the present hospital will be built, together with a cottage for pay patients who desire treatment. Improvements in the sanitary condition will also be made.

**Typhoid Fever in Alaska.**—Advices from Cape Nome, Alaska, brought by a steamship which left there October 6th, say that typhoid fever in severe form has broken out in the camp. More than two hundred and fifty patients were in the hospital, and five deaths had occurred.

**The Southern Surgical and Gynæcological Association.**—The annual meeting of this association will be held in New Orleans on Tuesday, Wednesday, and Thursday, December 5, 6, and 7, 1899. The president of the association is Dr. Joseph Taber Johnson, of Washington, and the secretary Dr. William E. B. Davis, of Birmingham, Ala., to whom intending readers of papers should send the title of the same.

**Petroleum as a Prophylactic of Malaria.**—It is reported from Sierra Leone that those who are engaged in investigating the mosquito theory of malaria in that district poured a drachm of kerosene oil, as an experiment, upon a puddle about a square yard in area, floating on which were numbers of Anopheles larvæ, with the result that after six hours all the larvæ were found to be dead.

**The Liverpool Tropical Expedition,** under the lead of Surgeon-Major Ronald Ross, has returned from West Africa. The members of the expedition report that there is every reason to hope that the country can be made entirely possible as a residence for Europeans. They say that other conditions are favorable to health, there is a good water supply, and if Europeans are careful both in their mode of living and house construction they will have every chance of health after the malarial mosquito has been exterminated. Only one member of the expedition suffered from malaria. He slept for one night without a mosquito bar, and was thus infected.

**The Question of an International Language** will seemingly not down, yet its solution is apparently as far off as ever. The *British Medical Journal* says that, on the invitation of the Prussian Academy of Sciences, delegates of all the European scientific academies have met in Wiesbaden for the discussion of some questions of international importance. Opinions are to be taken as to the possibility of establishing a uniform scientific language, and a uniform language for general

intercourse—Latin for the former, English for the latter. Whether this result will be attained by the Wiesbaden meeting, and whether it is attainable at all in our present multinational civilization, our contemporary thinks, is very questionable. "But the fact that distinguished and eminent representatives of science have come together from all European states and from America for the purpose of seeking a way toward the realization of more complete mutual understanding, thus forming, so to speak, a peace conference of science—this fact in itself is of the highest significance."

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 27, 1899. October 20th.—Medical Director M. C. Drennan promoted to medical inspector. Medical Inspector J. C. Wise ordered to duty as member of the naval examining-board, Washington, D. C., November 1st. Surgeon W. A. McClurg detached from duty as member of the naval examining-board, Washington, D. C., November 1st, and ordered home and to be ready for orders for sea service. October 21st.—Passed Assistant Surgeon C. E. Riggs ordered to the marine recruiting rendezvous, New York, November 1st. October 24th.—Medical Director M. C. Drennan retired October 24th, under section 1453 Revised Statutes and section 11 navy personnel law. October 25th.—Medical Director C. J. Cleborne detached from duty in charge of the naval hospital, Philadelphia, Pa., November 1st, and ordered to Washington, D. C., November 2d, for examination for retirement and then home to wait orders. Medical Inspector R. A. Marmion ordered to duty in charge of naval hospital, Philadelphia, Pa., November 1st. Passed Assistant Surgeon C. H. T. Lowndes detached from the *Princeton* and ordered home by the first public conveyance. Assistant Surgeon O. M. Eakins appointed from October 21st. October 26th.—Medical Director J. C. Boyd promoted to medical inspector. Assistant Surgeon R. C. Holcomb detached from duty at the Naval Academy, Annapolis, Md., and ordered to the *Solace*, November 9th, for duty in connection with battalion of marines for Manila. October 27th. —Assistant Surgeon R. Spear detached from the *New York* to home and sick leave two months. October 27th (changes from Asiatic station, by cablegram).—Assistant Surgeon M. V. Stone detached from the *Brutus* and ordered to the island of Guam.

**Dr. Richard Grady,** of Baltimore, has been appointed dentist to the Naval Academy, this appointment being the result of a competitive examination open to all dentists. There were more than thirty applicants from Baltimore and Washington, and one from California. The salary attached is $1,600. Dr. Grady is a graduate in medicine as well as in dentistry.

**Diphtheria** prevails to an unusual extent in many of the small towns in southern Ohio on the banks of the Ohio River, and in many of the places it has been found necessary to close the public schools. In Princeton, N. J., also the public schools have been closed because of the appearance of this disease in many parts of the town. Most of the cases reported have been of a mild type, and the deaths have been fewer.

**A Maryland Laryngological Society.**—The throat physicians of Maryland are about to form a Laryngological Society.

**A Thief in a Hospital.**—A man went to the Orange (N. J.) Memorial Hospital one day last week, and said he had been sent by the local electric company to see what repairs were needed by the electric-lighting system in the hospital, and also to measure the nurses' home for wiring. He was allowed to go through the place, making measurements, and apparently taking notes of defective lights and places where new lights were needed. But soon after he had finished his work and gone away it was found that he had taken money, watches, and jewelry, and whatever else was portable and of any value.

**Pathological Society of Philadelphia.**—At a stated meeting held October 26th, Dr. J. H. Lloyd exhibited a brain tumor in the antero-frontal region, of which symptoms had been present for four years, and most prominently hemiplegia, headache, frontal ataxia, astasia-abasia, but no convulsion. The tumor was an infiltrating growth, probably gliosarcoma. Dr. H. W. Cattell reported "A Case of Hypertrophic Cirrhosis of the Liver." Dr. M. H. Fussell exhibited specimens of mitral stenosis with renal calculus, in which distinctive symptoms were unobserved during life, although the lesions were marked, the ureter on the affected side being occluded and the kidney largely disorganized. Drs. De W. H. Sherman and W. G. Spiller reported "A Case of Acute Poliomyelencephalitis in an Adult," occurring in a medical student in the sequence of infection at autopsy. The inflammatory reaction was not strictly confined to the gray matter of the anterior horns and the basal ganglia, though most pronounced in these parts. The opinion was expressed that the disease might arise from the activity of any one of a number of bacteria. Drs. W. M. Welch and D. Riesman exhibited specimens from a case of typhus fever. The patient had been a Hungarian immigrant just arrived and received into the Municipal Hospital. The spleen was enlarged, the mediastinum was emphysematous, the kidneys were inflamed, and the liver exhibited focal necrosis. Bacteriologic examination of the heart's blood disclosed only the presence of the staphylococcus albus. The Widal reaction had yielded negative results. Dr. D. J. McCarthy read a communication entitled, "Iron Filtration in Ganglion Cells," reporting the results of a histological study of the brain from a case of central tumor, and the brain from a rabbit dead of experimental snake-poisoning, in both of which chromatolysis of the Purkinjé cells of the cerebellum was found. Dr. D. Riesman exhibited specimens from a young lioness dead in consequence of occlusion of the larynx by a large piece of meat. The organs were in a normal condition, but were interesting from the viewpoint of comparative anatomy.

**Obituary Notes.**—Dr. P. A. Boyer, chief burgess of Selin's Grove, Pa., died on October 23d, at the age of forty-three years. He was graduated from the medical department of the University of Pennsylvania in 1881, and was a member of the State board of vital statistics.—Dr. C. Russell L. Jakes, of Wilmington, Del., died suddenly of heart disease at Philadelphia, on October 26th, at the age of forty-five years. During the recent war he was assistant surgeon to the First Delaware regiment.—Dr. William R. Maddox, of Washington, D. C., died on October 25th, at his country residence near that city, from pulmonary hemorrhage. He was born in Erie, Pa., in 1854, and was graduated from the Jefferson Medical College in 1877.—Dr. Thomas Jefferson Jackson, of Springfield, N. J., died on October 26th, of disease of the heart, following pneumonia. He was born in Baltimore County, Md., in 1849, and was graduated from the College of Physicians and Surgeons, Baltimore, in the class of 1880.—Dr. Ernest Diese died at Philadelphia on October 30th, at the age of seventy-eight years. He was a graduate of the German University of Jena, but had lived and practised his profession in this county for forty-eight years.

## Surgical Suggestions.

**Diagnosis of Relaxation of the Pelvic Outlet.**—The following conditions which are of diagnostic importance are present: (1) Backward dislocation of the perineum; (2) bulging of the perineum, which diminishes or destroys the concavities in the perineum; (3) diminished resistance of the perineum on palpation; (4) protrusion of the recto-vaginal or vesico-vaginal walls.—J. T. Watkins.

**Treatment of Displacements of the Uterus by Operation: Based on Two Hundred Cases.**—If the uterus is too long, the cervix is amputated by the method of Schroeder; if chronically inflamed, it is dilated, curetted, and treated with rest, hot douches, iodine, boroglyceride tampon, until its size and weight are reduced. If the vaginal outlet is torn or relaxed, it is tightened up by means of anterior and posterior colporrhaphy. If it is absolutely certain that there are no adhesions, and that the tubes and ovaries are healthy, Alexander's operation is performed. If there is the slightest doubt as to the mobility of the uterus, ventro-fixation is chosen.—J. Lapthorn Smith.

**Treatment of Indolent Ulcers.**—Marcuse describes a method of treatment for troublesome ulcers of the leg which he has found more efficacious than elastic bandages or sticking-plaster In cases of large ulcers which have been neglected for a long time, and are constantly pouring out a copious secretion, or callous ulcer with sharp indurated edges, the author has found that the application of wet bandages moistened with Burow's solution, subsequently followed by the zinc-glycerin glue, has an excellent effect. The composition of the solution is as follows: Alum pulv., 5.0; plumb. acet., 25.0; aq. destil., 500.0. A more convenient form for use in general practice would be: Alum, 10 parts; plumb. acet., 50 parts; both powders to be well mixed in a litre of water. The application of this lotion is found to have an astringent action on the ulcer without causing dryness. It is antiseptic, and lessens tension and pain. The moist warmth in the case of the callous ulcer has a powerful effect in lessening the induration and improving the general vascularity of the part. The patient should be kept in bed for some weeks. The method of application consists in cutting a large piece of ordinary gauze dressing, so that the skin for several inches round the ulcer is covered. The gauze is moistened with the lotion and then applied, the whole being covered with gutta-percha tissue. After a short time sulphate of lead is precipitated.—*International Medical Magazine*, July.

**Indications for Cholecystectomy.**—(1) When, after cholecystotomy, the gall bladder is constricted and cannot be sutured to the parietes, and it is assumed that the comomn duct is clear; (2) when suppurative changes in the wall of the gall bladder have rendered suture impossible; (3) when there is complete obliteration of the cystic duct.—Robson.

**Gynæcological Hints.**—Give iron when the menses are scanty and lack color; give arsenic when the flow is too profuse, prolonged, or frequent.—Fordyce Barker.

Chronic leucorrhœa of long standing can be cured only by persevering in frequent local use of astringents through a speculum, together with hot vaginal injections.—Mundé.

All pelvic congestions are venous, and the term "chronic inflammation," so far as it applies to the organs in that cavity, is a misnomer, because the arterial vessels are not involved in that process.—Emmet.

The most common displacement of the ovary is dislocation downward into the retro-uterine pouch, to which the name of prolapse has been improperly given. —Tait.

Cancer of the womb usually begins on the vaginal portion of the cervix, and consequently has to bear the brunt of the insults of coition and parturition.—Goodell.

Tepid vaginal injections, so generally recommended and inadvertently used by patients in place of hot injections, have no positive therapeutic effect whatever. —Barnes.

**Epidemic Cerebro-Spinal Meningitis and Lumbar Puncture.**—Dr. J. L. Hirsch (*New York Medical Journal*, August 19th) says: "As to the therapeutic value of lumbar puncture all do not agree. By relieving abnormal pressure, and probably by getting rid of some of the toxins, the beneficial results can readily be conceived. The technique of the operation is simple and the pain to the patient is but slight. In children I have found the best position to be with the child lying on its right side and its back slightly arched, so that the spinous processes stand out prominently. Many prefer the child in the sitting position. The puncture is to be made between the second and third, or the third and fourth, lumbar vertebræ. The needle, from 5 to 8 cm. long, is thrust in about 1 to 2 mm. from the median line, so as to avoid the strong intraspinous ligament. When the needle is within the spinal canal its point can be felt to move freely; if the fluid does not flow spontaneously, slight suction may be made with a hypodermic syringe. Needless to add that all antiseptic precautions must be observed. A procedure so simple, so readily carried out, and so absolutely devoid of danger, has, I think, no contra-indications for diagnostic, if not for therapeutical purposes.

**Indications for Enucleation.**—Knapp (Norris and Oliver's System) mentions the following: (1) In intolerable pain with incurable blindness; (2) in pain, inflammation, hemorrhage, photopsia, and other irritative symptoms in chronic irido-cyclitis, glaucoma, phthisis bulbi, etc., in one eye, which is blind, or surely will be blind, irrespective of the other; (3) in eyes so extensively injured that a recovery is not to be thought of; (4) in intra-ocular malignant gliomas and sarcomas, except when they are small and situated in

the iris, so that they can be radically removed; (5) in epi-ocular malignant tumors, if they cannot be removed without destroying the eye, (6) in orbital tumors that threaten life, if it is impossible to remove them without sacrificing the eye; (7) in staphyloma and macropthalmus, if the eye is blind and becomes unsightly and troublesome, (8) in panophthalmitis, conditionally; (9) in the presence of foreign bodies in the eye that cannot be removed, and cause trouble, inflammation, and blindness; (10) in traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia.

**Hydrocele.**—In cases of complicated, doubtful, or old hydrocele, resection of the tunica vaginalis should be done. In simple cases, the injection method is preferable, using 5 cm. of pure tincture of iodine, after first emptying the sac and cocainizing.—MALHERBE.

**Condyloid Fractures.**—It has been my practice to treat these fractures with the elbow extended, and carefully to compare the injured with the sound limb, in order to preserve by my splints the humero-ulnar angle. The position advocated seems to relax the important displacing muscles.—JOHN R. ROBERTS.

**The Drainage Tube** will never be resumed in operations for cancer of the breast. It is a foreign body and only delays repair while admitting air to the wound. Seal up the wound with aristol collodion. Should suppuration occur in any portion, cleanse with peroxide of hydrogen, and apply tincture of iodine to the pus cavity.—DANIEL LEWIS.

**Radical Cure of Hernia.**—When we consider the high percentage of cures and practical freedom from danger in these operations; that a patient may in two weeks, without pain and with little inconvenience, be freed from the danger of strangulation, the burden of a truss, and the constant sense of insecurity—when we consider these facts, it is incomprehensible that all physicians do not advise the radical cure for all their patients, except those rare cases in which, for special reasons, operation is contraindicated.—BUCHANAN, of Pittsburg.

**Pyelitis.**—The modern treatment for pyelitis will remain, after medical means fail, incision and drainage; if this fails, nephrectomy. Some have favored primary nephrectomy, because the secondary, when the fatty capsule has changed into fibrous tissue and intimate adhesions have formed, is more difficult of execution, but the danger of nephrectomy is certainly greater than that of nephrotomy, and many a kidney which seemed doomed has resumed its work entirely or partially at least.—MARCELL HARTWIG, *Buffalo Medical Journal*, January.

**Appendicitis.**—Dr. Carl Beck sums up the following conclusions (*Sammlung klinischer Vorträge*, No. 221): (1) Appendicitis is a surgical disease and should be treated surgically as soon as diagnosed. (2) Since it is impossible in the early stage to estimate the virulence of the infection, the best therapy is the removal of the appendix. (3) If the patient objects, the opium treatment is to be adopted, and after the attack the patient should be impressed with the necessity of an operation. (4) If a competent surgeon is not at hand, or the surroundings are unfavorable, the expectant treatment is to be adopted and an operation performed later. (5) In consideration of the fact that the mortality of a simple appendectomy is almost *nil*, the operation should be strongly advised after the first attack.

**Pelvic Abscess.**—The objections that may be reasonably urged against the vaginal route is that it is necessary to depend upon the sense of touch altogether; it is work in the dark. In pelvic abscess, when it is found necessary to remove adherent appendages, the operation through the vagina is very difficult, and injury to the intestines and ureters is likely to occur. In cases in which the abscess reaches low in the pelvis, pointing into Douglas' pouch, I certainly would prefer the vaginal route, believing that there would be less danger of infecting the general peritoneal cavity in operating through the vagina. Mere incision and drainage should be practised only in desperate cases, in which the condition of the patient will not admit of a more formidable operation. Patients quite often make a complete recovery from incision, irrigation, and drainage; but as it is often found necessary to operate the second time to complete the cure, it is always advisable, when the condition of the patient will admit, to make a complete operation at first. Pus cases do not stand well prolonged anæsthesia and shock, so it is very necessary to operate quickly, and I recommend thorough irrigation and drainage.—O. B. CAMPBELL, *New York Medical Times*.

**A Few Points Concerning Chloroform Anæsthesia.**—Dr. A. Paul Heineck (*Medical Standard*, July) says: (1) Always reduce to the minimum consistent with full and complete anæsthesia the amount of chloroform vapor inhaled. Do not administer chloroform from a towel. An overdose is too easily given this way. By autopsies and experiments, Heintz has proven that chloroform inhaled for long periods produces, through a slow secondary action, pathological changes in the organs, capable of causing death, one or several days after the anæsthesia. By lessening the dose of chloroform the liability to undesirable after-effects is lessened.

(2) Avoid the continuous action of chloroform on the organs by allowing at least one week to elapse between two chloroformizations in the same individual. The elimination of chloroform inhaled is completely effected only in about a week. The secondary action of chloroform exhausts itself also in about a week. Both elimination of the chloroform inhaled and its secondary action must be at an end before more chloroform is introduced in the system.

(3) Always be very watchful while administering chloroform to individuals suffering from renal or hepatic insufficiency. These subjects offer to chloroform, as they also do to other intoxicants, as, for instance, sepsis, an impaired resistance.

(4) Use an Esmarch inhaler in administering chloroform. Give this agent well diluted with air. Give it drop by drop. Danger of an overdose is thereby lessened. "Quantity is the all-important factor in chloroform anæsthesia. I am convinced that death is nearly always due to unskilful administration, and that unskilful administration is the administration of an overdose" (Waller). Chloroform should always be given with about ninety-five per cent. of air. At the beginning of anæsthesia hold the inhaler some inches from the mouth and nose, so that the chloroform will be diluted with air. By doing this the sense of suffocation which is so trying to the patient, and so provocative of struggling, will often be prevented. Asphyxia taking place within a few minutes from the commencement of the anæsthesia can be caused by a too highly concentrated vapor of chloroform. If the patient struggles violently, breathes irregularly, or holds his breath, remove the cap and have the patient take a breath of fresh air before the administration is proceeded with.

(5) The following conditions, occurring under chloroform anæsthesia, are signs of impending danger: (*a*) Sudden dilatation of the pupil; (*b*) shallow, sighing respirations, (*c*) absence of pulse, rapid, irregular or intermittent pulse; (*d*) sudden paleness or sudden lividity of countenance.

# Society Reports.

## NEW YORK STATE MEDICAL ASSOCIATION.

*Sixteenth Annual Meeting, Held in the New York Academy of Medicine, October 24, 25, and 26, 1899.*

JOSEPH D. BRYANT, M.D., OF NEW YORK, PRESIDENT.

*Third Day—Thursday, October 26th.*

(Concluded from page 644.)

**The Sphere of Drainage in Surgery of the Appendix.**—DR. WILLIAM STEVENSON MACLAREN, of Litchfield, Conn., read this paper (see page 617).

**Appendicitis—Its Treatment from a Medical and Surgical Standpoint.**—DR. THOMAS B. SCULLY, of Oneida County, was the author of this paper. He said that if more attention was paid to the cause of appendicitis there would be less confusion regarding the best treatment to be pursued. He favored the administration, in the early stages, of divided doses of calomel and soda, and the use of a high enema, given by the physician or by an experienced nurse. He also advocated the use of cold applications. While not objecting to the use of morphine in the early stages, he preferred to combine it with strychnine, giving them hypodermically. The locking up of the secretions would be overcome by this combination with strychnine. He had not found that this treatment masked the symptoms or led the physician astray. However, if there were no signs of amelioration after the first twenty-four hours, the physician should call a surgeon to his aid. He was of the opinion that when operation seemed to be demanded the appendix should be removed in all cases in which this was possible. He did not think an inch-and-a-half incision was any safer than one twice that length. He was of the opinion that too many sutures were used in approximating the peritoneum and the other layers of tissue, and that these tended to strangulate the circulation in the parts. Peroxide of hydrogen acted beautifully as a disinfectant within the cavity.

DR. ROCHESTER thought the author had been inconsistent in advising morphine, strychnine, and sulphate of magnesia. If sulphate of magnesia was to be used, morphine should be withheld, and the combination of morphine with strychnine did not seem rational, because the morphine was intended to quiet peristalsis, while strychnine would excite this muscular action of the bowel. Personally, he was one of those who believed that acute appendicitis should not be operated on in the acute stage, but should be treated with large doses of morphine, according to the old method of Alonzo Clark. The morphine should be given in doses not merely sufficient to quiet pain but to reduce the respirations to four or eight per minute. Cases were cited from his own experience, to prove the excellent results obtainable by this method.

DR. EDEN V. DELPHEY, of New York, said that it was not always a question of when or how to operate in appendicitis, but whether or not to operate, and proceeded to give cases illustrative of this point.

DR. LEROY J. BROOKS, of Norwich, pointed out some of the difficulties in the way of early operation in country practice.

DR. SCULLY, in closing the discussion, said that morphine was commonly given with atropine, and it was the latter that was chiefly responsible for the locking up of the secretions. The opium treatment was not in accord with the view commonly held by physicians of the present day, that the cleaning out of the intestinal tract was the great desideratum. By giving morphine with strychnine the nervous irritability of the sufferer would be allayed without interfering with intestinal peristalsis or locking up the secretions.

**Cholangiostomy, with Report of Two Successful Cases.**—DR. MERRILL RICKETTS, of Cincinnati presented a brief paper with this title. Its object was to consider hepatostomy for the sole purpose of removing biliary concretions contained within the intrahepatic bile ducts and bladder, and to report two hepatostomies on the human being, one for exploration and the other for the removal of a concretion within the biliary bladder. He stated that while incision into the liver for the evacuation of a pus cavity had become an established procedure incision into hepatic tissue for the purpose of extracting concretions had been limited to only three or four cases. In cases of hepatic abscess the liver was softened and much more congested than when incision was practised for the extraction of concretions; moreover, it was highly probable that the hepatic abscess had been so walled off as to prevent, to a great degree, interstitial hemorrhage. Intrahepatic ligation could be resorted to, if necessary, in cases of excessive hemorrhage. The operation of hepatostomy might be required in the following conditions: (1) When the gall bladder was contracted upon one or more concretions, or when it was desirable to explore an atrophied biliary cyst that could not be sutured within the abdominal incision, and where cholecystectomy was not necessary or advisable; (2) when, from any cause the lobe of the liver was too large to allow the gall bladder to be brought into the abdominal incision for suturing, (3) when one or more concretions had escaped from the biliary tract into the liver substance; (4) when one or more concretions had become encysted or impacted within the intrahepatic ducts, (5) when the common and cystic ducts had become occluded by a new growth, or the common duct had become occluded by a new growth and the gall bladder atrophied to such a degree as to prevent cholecystenterostomy or cholecystotomy; (6) when, before or after opening the peritoneal cavity, it was found that a hepatic abscess had ruptured into the biliary tract, filling the gall bladder with pus that could not freely escape through the common duct. It was advised that the operation be done in two sittings, the object of the first being to reach the capsule, and of the second to enter the liver tissue after sufficient time had been given for the cut edges of the peritoneum to become adherent to the capsule—ordinarily an interval of three or four days.

**The Differential Diagnosis between Chronic Joint Disease and Traumatic Neurosis.**—DR. REGINALD H. SAVRE, of New York, presented this communication. He said that cases in which there was no joint inflammation often presented symptoms so much like arthritis as to mislead even experienced physicians. Such mistakes were largely the result of carelessness in making the examination or in eliciting the history. Many cases of injury were followed by affections of the nervous system, even when there was no legal suit involved. In cases of true joint disease one of the best guides to the extent of the destructive process in the bone was the thermometer. If the inflammation was superficial the local rise of temperature could often be appreciated by the hand. One of the first symptoms of an inflammation of a joint was involuntary spasm of the muscles controlling that joint. One of the peculiarities of this spasm was that passive motion could often be made through a certain distance without causing pain. If in a spinal case there was tenderness along the whole of the spine, it almost certainly indicated the neurotic nature of the affection. The facial expression of the neurotic pa-

tient would often prove a useful aid in diagnosis. The chief points to remember were: (1) Neurosis was apt to follow injury sooner than joint disease; (2) the temperature was usually lowered in a neurosis, and elevated in inflammation of a joint; (3) the local temperature was usually much lower in cases of neurosis than in joint disease; (4) atrophy progressed more rapidly after injury to a nerve, (5) true muscular spasm was not present except in joint disease, though it may be simulated.

**Subnormal Temperature.**—Dr. Leroy J. Brooks, of Norwich, presented this paper, which was a continuation of one read at the last annual meeting. The paper dealt with the possible value of a subnormal temperature as a means of predicting a recurrence of melancholia, epileptic attacks, dipsomania, and nervous exhaustion, and discussed the various forms of toxæmia and autointoxication and their relation to lowered body temperature.

Dr. Edward D. Fisher, of New York, in discussing the paper, said that, among physicians in hospitals for the insane, it had been generally conceded that insanity, as a rule, ran a non-febrile course, with the exception of attacks of acute mania. In cases of melancholia, stuporous insanity, or dementia—in other words, in those characterized by very little activity—the body temperature was apt to be slightly below the normal. It was well known that, in the normal individual, muscular exercise was associated with a certain rise of temperature, and there was good authority for the statement that this increased temperature was dependent upon muscular action. According to his experience, the study of the body temperature in the insane had afforded very little information as to the onset or recurrence of an attack. The temperature changes in epileptics were not of sufficient importance to serve as a guide to the physician as to the approach of a seizure. In the ordinary epileptic there was rarely a perceptible rise of temperature; elevations of temperature were observed chiefly in those cases in which the convulsions succeeded one another quite rapidly, and gave rise to the condition known as the *status epilepticus*. The elevation or depression of the temperature of the body did not seem to be an important factor in either nervous or mental diseases, and its occurrence could be explained by intercurrent maladies or by too little or too great muscular activity.

**Etiological Relation of Auto-Infection and Auto-Intoxication to Diseases of the Eye.**—Dr. Alvin A. Hubbell, of Buffalo, read this paper. He said that by auto-intoxication was meant a self-poisoning, whether by excess or retention of normal products, or by abnormal products generated in the body. Auto-infection, on the other hand, was a direct germ invasion. Uricacidæmia was probably an example of an auto-intoxication resulting from an accumulation of a normal product. An excess of the secretion of the thyroid gland was now thought by many to explain the condition known as exophthalmic goitre. Retinitis might always be regarded as the result of some poison circulating in the blood. Optic neuritis, both in its papillary and retrobular forms, was distinctly a toxic affection. He believed that sympathetic ophthalmia furnished another illustration of auto-infection or auto-intoxication, not in the sense that germs were transported from the injured eye to the sound eye, but in the sense that the uveal tract of the sound eye, by the lowering of its vitality through the extreme reflex and vasomotor disturbance kept up by the foreign body in it, so injured the other eye that it became a true poison, and induced a most obstinate and uncontrollable inflammation.

**The Effects of Certain Occupations on the Pharynx.**—Dr. Seymour Oppenheimer, of New York, was the author of this paper. The paper was based upon a study of fifty cases, a familiar type being the granular pharyngitis and congested larynx of the public speaker. The age of the patient did not, in itself, bear any relation to the development of catarrhal affections of the laryngeal mucosa, but the statements of those engaged in such occupations as weaving showed quite clearly that the younger the person at the time of entering upon such an occupation, the greater the liability to ill effects. The inhalation of dust vapors and chemical agents were the most important exciting causes. The changes so produced were those of acute congestion and inflammation, and the resulting pharyngitis differed in no way from the ordinary form. Those already affected with pharyngitis before beginning such work were naturally those who suffered first and most severely from the irritation produced by their special occupation.

Dr. George B. Hope, of New York, said that there was no course of local treatment which would meet more than a comparatively limited number of such cases, in the majority, more could be accomplished through constitutional than local medication.

Dr. Robert C. Myles and Dr. Henry Risch continued the discussion, taking the ground that neglected pathological conditions of the upper respiratory passages were very important predisposing factors. The individual differences in irritability were also dwelt upon.

**The Topical Application of Iodoform in the Treatment of Tuberculous Peritonitis**—Dr. Zera J. Lusk, of Warsaw, contributed this paper. He was of the opinion that in topical application of iodoform was to be found a most potent means of treating tuberculous peritonitis. The method consisted in the application of the remedy in the form of an "iodoform poultice." Illustrative cases were narrated.

**An Epidemic of Intercostal Neuralgia.**—Dr. Thomas F. Reilly, of New York, read a communication on this subject. The paper was founded on a series of fourteen cases, seen last summer within a period of five weeks, which had been characterized by chilliness and malaise, lasting for a few hours, and followed by pain along the intercostal nerves. This had increased rapidly in intensity, and had been associated with a mild febrile movement. After three or four hours the pain had disappeared and the temperature dropped. At the same hour on the following day the pain would recur, and after three or four days there would be, in most cases, a profuse herpetic eruption. The spleen had not been enlarged in any cases. In four of the cases the herpes had been along the course of the intercostal nerves; in eight it had been on the face. Pruritus of the entire body had been observed in several of the cases. Obstinate constipation had been a marked feature in nearly all. All the cases examined for leucocytosis had shown this condition to be present. In none had there been the tender point characteristic of ordinary intercostal neuralgia. Three cases had occurred in one house, two in another, and two in still another house. The mean temperature of the atmosphere, according to the report of the local forecaster, had been slightly low for this period, but there had been no unusual meteorological conditions. Quinine had seemed to have no effect, and a previous malarial history had been wanting. A very similar epidemic had been reported, the speaker said, in a small German city, and had comprised about one hundred cases. The reporter of these cases was of the opinion that it was an acute infectious disease. Strapping of the thorax with rubber plaster had given great relief in those cases in which there had been no eruption of herpes zoster present in this region.

**Suppurative Ethmoiditis and Its Treatment.**—Dr. Frank S. Milbury, of Brooklyn, read this paper.

He stated that severe ethmoiditis was often followed by necrosis. All parts of the ethmoid might be inflamed, but when the inflammation went on to suppuration the affection became most formidable. The antrum was implicated in over fifty per cent. Personally he had found suppurative ethmoiditis rather frequent and necrosis quite rare. The pain was usually referred to the base of the nose and under the orbit, or to the back of the eyeball. If a simple inflammation, it usually subsided spontaneously, but the suppurative form sometimes lasted for months or years. The treatment should consist in cleansing the nasal cavity with some antiseptic solution and in removing all obstructions to free drainage. The wholesale removal of the turbinates was absolutely uncalled for. Recent cases would respond rather quickly to treatment, but those of two or more years' standing were extremely obstinate, and he was doubtful if complete recovery took place at all. In his thirty-nine cases the maxillary sinus had been involved in sixteen.

Dr. Francis J. Quinlan, of New York, said that it was to be regretted that many specialists did not dwell sufficiently on the conditions of the system leading up to these so-called vascular hypertrophies and their attendant evils. Personally he believed that many of these hypertrophies of the nasal fossæ, as well as lymphoid thickenings of the base of the tongue, were, in a great many instances, due to some deterioration of the health, and especially to the uric-acid diathesis Under constitutional treatment, many of these enormous vascular hypertrophies would tone down, the spaces would open up, and the normal drainage would be restored. The importance of securing this was obvious to those who fully appreciated the important respiratory function of the nose.

Dr. Robert C. Myles called attention to the necessity for sharply distinguishing between unilateral and bilateral suppurative ethmoiditis. Double chronic suppurative ethmoiditis was usually the result of polypoid degeneration of the ethmoid bone. Here the original cause was evidently some structural change in the bone, resulting in a passive or watery œdema, which, in turn, gave rise to polypoid change and sufficient interference with the nutrition of the bone to lead to its destruction. If suppuration occurred, it was absolutely necessary to remove all polypoid growth and penetrate the cells in such a way as to secure good drainage within the cells. The best method of doing this was to remove part of the middle turbinate, especially the anterior part, and curette carefully. A very fine silver cannula should then be inserted, and through it a mixture of vaseline and iodoform be injected. This remedy had no equal in these cases. In all cases of cystic formation the cells should be opened. The bone would be found rough in polypoid cases, but it was not really necrosed. The speaker predicted that in the future drainage would be secured by the aid of an external incision. He had adopted this plan in two or three instances with much satisfaction, and greatly preferred it to the internal method.

**Poisoning of Soldiers at Aldershot.**—The American soldiers are not the only ones who suffer from the ill-effects of canned meat. Embalmed beef or tinned food of some description has been playing havoc with the digestive organs of members of the British army. The Aldershot correspondent of *The Central News* reports that considerable apprehension has been caused among the military authorities there at the strange deaths of several soldiers who had recently returned from the Salisbury Plain manœuvres. Two men died recently with all the symptoms of ptomain poisoning.

## ANTISEPTIC GAUZE.

By G. W. TYRRELL, M.D.,
PERTH AMBOY, N. J.

One of my medical friends having told me that a simple procedure of mine might be of some use to others in the fraternity, I am encouraged to publish a description of the same. The procedure is simply a method of preparing gauze for application to suppurating and like surfaces. I first take a sufficient quantity of cotton-seed oil and add carbolic acid or other antiseptic in quantities sufficient to make the strength of solution desired. This I bring to a very high temperature over a water bath and maintain this temperature quite some time. Then taking some aseptic gauze folded conveniently for subsequent use, I immerse it in this hot mixture. After it has become saturated it is removed and squeezed out in a heavy press under probably three hundred pounds' pressure. This squeezes out nearly all the oil, but leaves the gauze with every fibre sufficiently greasy to prevent its sticking to any surface to which it may be applied. Any physician who has to deal with many large granulating surfaces, as for instance after the removal of a cancerous breast, will, I think, save much time and be greatly pleased with gauze prepared in this manner. He will also obtain much better results than by applying to the surface quantities of foreign matter which must ultimately be thrown off before the healing-process is perfected. I believe this method is more convenient than gradually removing dressings with $H_2O_2$ or any other antiseptic solution, and I feel confident that the satisfaction experienced by the patient will equal that of the surgeon.

## VOLVULUS OF THE CÆCUM.

By G. H. COOMBS, M.D.,
WALDOBORO, ME.

At 10 P.M., July 23d, the writer saw with Dr. Strickland, of Washington, Me., a patient with the following history. The case was one of a woman aged thirty-six years, able to perform alone the laborious duties of a farmer's wife, an epileptic, with seizures limited to mild nocturnal attacks during the past few years, and with a history of a short attack of acute mania three years before. She was the mother of three healthy boys. At about 2 P.M., July 21st, she was awakened, after a short nap, by a severe paroxysmal pain beneath an area three inches in diameter just to the left of the umbilicus, attended with vomiting of the contents of the stomach only, which soon ceased; the pain was somewhat controlled by household remedies. Several doses of Epsom salts were taken the following day because of constipation, but without result.

On the forenoon of the 23d, nearly forty-eight hours after the onset of the pain, Dr. Strickland was called and found her suffering severe paroxysmal pain; the temperature was normal, pulse 84; there was no vomiting The right side of the abdomen was flattened, not sensitive; on the left, from a little above the umbilicus to three inches below it, the abdomen was very prominent, tympanitic, and quite sensitive. The menstrual history was peculiar and suggested the possibility of extra-uterine pregnancy as a factor.

A high rectal injection of Epsom salts and glycerin in hot water was administered; it was retained twenty minutes and was expelled with a large quantity of fæces, after which the woman was more comfortable. Morphine gr. $\frac{1}{4}$ and atropine gr. $\frac{1}{150}$ were then given

hypodermically, and instructions were left to use a warm rectal injection a few hours later, arrangements meanwhile being made for a consultation. This enema resulted in a copious fecal discharge which afforded great relief.

Living fourteen miles distant by carriage, I was unable to reach the patient until 10 P.M., and then found her so much relieved that she ridiculed the idea of a consultation. At that hour the pulse was 90, temperature 99.4° F.; the abdomen showed a more even distention on both sides than at Dr. Strickland's first visit, though there was still a little more prominence on the left than on the right side, while the latter was more sensitive. The left side of the abdomen was very tympanitic, and there was no shading to dulness at any point. Vaginal and rectal examinations gave negative results except that the cervix uteri was unusually soft for a non-pregnant uterus. Finally deciding to await developments, I returned to my home, but was again called at 7:30 A.M., on the 24th, and reached the patient in company with a trained nurse at about 10 o'clock. I found her condition much worse in every respect, there being a great increase in the soreness, abdominal distention, and paroxysms of pain, the increase having begun rather suddenly at 5 A.M. The temperature was 100° F., pulse 96.

I operated at 11 A.M., seventy hours after the initial symptoms, assisted by Dr. Strickland; Dr. Wood, of Union, anæsthetizing the patient. The usual precautions, so far as time and locality permitted, were made to secure asepsis. The median incision was necessarily long on account of the intestinal distention. The intestines were found to be much inflamed. Search revealed the cæcum with a normal appendix in the left lower quadrant of the abdominal cavity. It had undergone complete rotation on its own axis. Finding that reversal of this rotation did not result in an emptying of the cæcum naturally, I incised it at a point where its peritoneal coat had ruptured and been stripped off, and removed nearly three pints of liquid fæces, a large amount of gas first escaping. The patient had failed so rapidly that an attempt to anchor the cæcum was not deemed expedient, and the intestinal incision was closed; the loosened peritoneal coat at this point was sutured, a second peritoneal tear two inches in length was also sutured, and after copious irrigation of the abdominal cavity the intestines were replaced and the external wound was closed.

The patient's condition was bad, the pulse being about 140 for forty-eight hours in spite of stimulation to the limit, the temperature rapidly rising to 104° F., and remaining at that point for forty eight hours. At that time the woman became violently maniacal, attempting to tear off the dressings and get at the wound. A restful sleep was secured by a large dose of bromide of potassium, chloral, and hyoscyamus, administered by catheter through the nostril, these being used because of their prompt action in the previous attack. On awakening, the patient was much improved and thenceforward made an uneventful recovery under Dr. Strickland's care. The wound healed by first intention throughout. The bowels moved slightly on the first day, when a rectal tube was passed to aid expulsion of the gas, and naturally after the second day without resort to cathartics. Normal menstruation began within twenty-four hours after the operation. Strychnine stimulation was exchanged for digitalin and whiskey at the onset of the mania, and to this change part of the gain at this point seems to have been due. Interest attaches to the relief afforded by the high rectal injection, to the nervous history of the patient, and to the nervous post-operative complications, as well as to the involvement of the cæcum, its complete transposition to the left side, and its narrow escape from intra-abdominal rupture.

## Therapeutic Hints.

**Acute Nephritis.—**

℞ Tinct. digitalis ..... ʒ ss.
Liq. ammon. acetat ..... ʒ iss.
Spir. æther. nitrosi ..... ʒ ij.
Syr. tolutani ..... ʒ ss.
Aquæ cari ..... q.s. ad ʒ iij.
M. S. Teaspoonful every two hours to a child six years old.

—Goodhart and Starr.

**A Diuretic Wine in Chronic Nephritis.—**

℞ Juniper. contus ..... ʒ x.
Pulv. digital ..... ʒ ij.
Pulv. scillæ ..... ʒ i.
Vini Xerici ..... O i.
After macerating for four days add:
Potassii acetatis ..... ʒ iij.
M. Express and filter. S. A tablespoonful three times daily to an adult.

—Trousseau.

**Vomiting in Scarlatina.—**

℞ Tinct. gelsemii ..... ʒ ss.
Aq. calcis,
Aq. cinnamomi ..... āā ʒ i.
M. S. A teaspoonful every hour.

—Hatfield.

**For Senile Heart.—**

℞ Ac. arsenosi ..... gr. $\frac{1}{100}$–$\frac{1}{50}$

—Balfour.

**Toothache.—**

℞ Hydrochlorate of cocaine ..... gr. iss
Menthol,
Carbolic acid (crys.) ..... āā gr. xv.
Oil of cloves ..... ♏ v.
Camphorated alcohol ..... ʒ ij.
M.

Or:

℞ Orthoform,
Carbolic acid ..... āā gr. xv.
Camphor,
Chloral hydrate ..... āā ʒ i.
M. S. Pack cavity with cotton saturated with one of the above preparations.

—Dauchez.

**Liquor Thymolis Compositus (B.P.).—**

| | |
|---|---|
| ℞ Benzoic acid | 10 gm. |
| Boric acid | 20 " |
| Borax | 10 " |
| Thymol | 2 " |
| Eucalyptol | gtt. x. |
| Oil of wintergreen | " x. |
| Oil of peppermint | " vi. |
| Glycerin | 100 c.c. |
| Alcohol (90 per cent.) | 300 c.c. |
| Water | A sufficient quantity. |

**The True Value of Gargling.**—By gargling in the usual way only the upper anterior surface of the uvula and soft palate and base of the tongue are reached. The method of holding the nose and throwing the head well back when gargling enables the fluid to reach every surface of the pharynx.

The value of the two methods can readily be tested by painting the posterior wall of the pharynx with a strong solution of methylene blue. After gargling with water in the usual way, the latter will be perfectly clear and unstained; then let the patient gargle again by the method suggested, and the ejected fluid will be found stained.—*Editorial, Charlotte Medical Journal.*

**Typhoid Fever with Constipation.**—Dr. F. P. Henry (*Dunglison's College and Clinical Record*) recommends the use of saline cathartics, such as sulphate of magnesia, or citrate of magnesia, or Hunyadi water. He says purgatives may do harm; castor oil is bland when applied topically to an ulcer; but when taken by mouth produces increased peristalsis. The Peyer patches are infiltrated in typhoid fever. If you

choke off the circulation to these glands suddenly, you would cause sloughing. The molecular disintegration which is going on might be converted into dangerous sloughing. Now, in increasing peristalsis you constrict the vessels, choke off the circulation, and perhaps produce sloughing. So you must avoid increasing the peristalsis, in other words, avoid such cathartics as castor oil and use salines in preference.

**Pneumonia.**—The most successful treatment consists in giving a patient a hot-water bath. When nothing better was at hand I have often called for a tea-kettleful of boiling hot water and a bucket of cold water, a wash-basin, and a bath or large wash-tub. Seating the patient on a stool in the tub, covered with a sheet, having the water mixed in a wash-basin, as hot as it can be borne, I ladle it on the sheet covering the patient. From the tea-kettle of boiling water and the pail of cold water the wash-basin is kept replenished. The hot bath is kept up for thirty or forty minutes. If the patient complains of suffocation, cut a hole in the sheet and let his nose out. While under this simple operation patients by inhaling the hot vapor will expectorate a large amount of mucus, and sometimes more or less blood The heart action is improved and the dyspnœa is greatly relieved, in short, you have respited the patient and gained time for the operation of medicine.—Dr. A. Chase (*Pacific Medical Journal*, September).

**Rotation of Drugs.**—Dr. William Ewart read a paper at the sixty-sixth meeting of the British Medical Association on "The Alternating Administration of Drugs by Rotation as a Practical Principle of Treatment," from which the following conclusions are taken: (1) Some drugs—and these are chiefly the stimulants and the sedatives—lose more and more of their effect the longer they are continued (2) Other drugs, being slowly eliminated or distinctly cumulative, acquire through prolonged administration an increased activity, and in some instances a modified, and sometimes a dangerous action. (3) The most active dose, in the case of any stimulant or sedative and in that of many tonics, is (putting aside summation of doses or of their effects) the first dose. These considerations have led the writer more and more to the adoption of a principle which may be regarded as novel, less in itself than in its practical application, that of a systematic "rotation of drugs," not unlike the farmer's "rotation of crops." Patients may often be placed with advantage under the joint influence of several drugs; but they will derive most benefit from a frequent renewal (thanks to intervening breaks) of the first impression which had been produced by each drug.

**Treatment of Asthma.**—The inhalation of the fumes of burning nitre paper or specially prepared powders, or of cigarettes, is the popular remedy for the attacks of asthma. In many cases they give relief, in some marked relief. The powders consist of stramonium and nitre chiefly; the one we use at the hospital contains one part each of anise and nitre, two parts of stramonium leaves, and five grains of tobacco to the ounce; one teaspoonful is to be burnt on a plate and the fumes inhaled. The cigarettes used are a manufactured article containing stramonium leaves, nitre, and tobacco; they relieve the attacks sometimes when the powder fails. A pill containing gr. $\frac{1}{6}$ – $\frac{1}{4}$ of morphine, with gr. $\frac{1}{60}$ of atropine sulphate, given at bedtime, is sometimes useful. Extract of stramonium (gr. $\frac{1}{4}$) may be substituted for the atropine. I have not found the ethereal tincture of lobelia very useful; but I have not tried it in the way recommended by Hyde Salter, namely, in repeated small doses before the attack is expected.—Sidney Martin.

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE PROVINCIAL SCHOOLS, ADDRESSES BY SIR T. W. GAIRDNER, DR BYROM BRAMWELL, PROFESSOR HUGHES, AND SIR J. CRICHTON-BROWNE—MEDICAL SOCIETY OF LONDON, OPENING ADDRESS, SERUM THERAPEUTICS —CONFERENCE ON HOSPITAL REFORM.

London, October 13, 1899

The provincial schools carry on an able rivalry with their metropolitan competitors, and most of them have retained the custom of an introductory lecture. As on former occasions, several of them have invited distinguished persons from a distance to discharge this function, and they have been the gainers. Thus, this year, Sir W. T. Gairdner discoursed at Birmingham on "The Two Disciplines in Education," maintaining the importance of objective as against subjective teaching. Not that he undervalues the humanities; as a university professor how should he? But as a clinical teacher he knows the importance of practical work.

Dr. Byrom Bramwell went to Leeds and lectured on "The Progress of Medicine during the last Thirty-five Years," the time that has elapsed since he began his studentship, and Professor A. W. Hughes, of Kings College, went to Cardiff, at the invitation of his former colleagues, and delivered the inaugural lecture.

But the most notable of all these addresses in London or the provinces was that delivered at Owens College by Sir James Crichton-Browne, who took for his subject "The Quest of the Ideal." Speaking to the students as one who had travelled along the road himself, he warned them not to lose their ideals in the tendencies to materialism by which they would be surrounded, for their studies ranged over so vast or wide a field of empirical knowledge, so closely packed with facts and hide-bound by law, that there seemed little room left for the ideal. The loss of a man's ideal he regarded as a personal calamity. "That way madness lies," he said, as those engaged in his own department of practice are not seldom made aware. Yet the loss of the ideal is inevitable, if the only solution of the world-problem is materialism, for that reduces all things to the pull of opposing atoms, making intellect the activity of nerve cells, virtue, honor, and duty forms of selfishness, and heroism a kind of disease. "When the stewardess of the *Stella*—glorious woman!—took off her life-belt and gave it to an affrighted being beside her, and bravely sank, commending her soul to God, her act was not conducive to the preservation of the individual or the species It was an expression, we are told, of the abnormal over-functioning of a certain portion of her brain. Does not the heart sink and the gorge rise at such revolting nonsense?" Sir J. Crichton Browne exhorted his hearers to hold fast by idealism, which in some shape or other, however smothered up, dwells in every one, and went on to show that materialistic assumptions are still open to refutation Wide as the sphere of science is, it is limited in all directions. On no side does it begin at the beginning or end at the end, for, as Max Muller said, "Our minds are not so made as to grasp either beginnings or endings" Everywhere, said the lecturer, it is possible to leave the confines of science behind, and to come on unexplored regions beyond the pale, where the ideal is supreme, where poets and philosophers may expatiate at large. There are wavelengths beyond the red and violet to which the retina does not respond, vibrations beyond those the ear can catch. It is certain there is an uncircumscribed

physical universe of which we have no cognizance. It is equally certain that in the mental universe there are boundless areas which may be designated by contradictory terms, as our entrance to them is barred by self-contradiction in thought We can conceive neither of boundless space, nor of space without bounds, nor of an ultimate atom which is not both divisible and indivisible at one and the same time. What we call our intellect rests on our belief, not on our knowledge. Science cannot demonstrate the existence of a material world nor prove the existence of mind in our fellowmen, yet these are our rooted convictions! Having touched on similar metempirical regions, the lecturer passed on to consider three unfathomable chasms that yawn within the bounds of science and the existence of which is inconsistent with materialism. These chasms are that between the organic and the inorganic, that between the physical and vital, that between mind and matter, which is widest of all. As to this he referred to the fashionable materialistic notion of neural currents encountering resistance and causing the cells to glow like an incandescent lamp which is merely shirking the materialistic theory by taking shelter under a metaphor, and so blinking the chasm which gapes huge and impassable as ever, for of nerve cells in a glow or at a white heat we know nothing. Neural facts we know, and mental facts we know but there is no bridge between them, they cannot be identified any more than can a telegraph wire with the meaning of the message it transmits An idea and a vibration in nerve molecules are as essentially different as the multiplication table and the slate on which it is jotted down.

The lecturer concluded with the wish that his hearers, while immersed in the realities of life, might be rewarded in their quest of the ideal—a talisman that once seized and pressed to the breast would enable them to say to pessimism, "Avaunt!" and to beneficence, 'Open sesame." Negation is a barren wilderness, belief a teeming garden.

The medical societies as well as the schools resume work in October. On Monday the oldest, the Medical Society of London, opened its one hundred and twenty-seventh session. Dr. F. T. Roberts gave his presidential address. He said it would be inhuman to expect him, when every one is talking about the close of the century, not to take advantage of the inaugural meeting of the last session of the century in selecting a topic. So having stated that he began his medical life in the early part of the latter half of the century by apprenticeship, and that he had never regretted and was always grateful for the experience thus acquired, he passed on to his retrospect. Assuming that his hearers would agree with him that vast strides in progress had been made, the president indicated some of the agencies by which this was brought about. Foremost of these he ranked the advance in general education and culture, and the adoption of scientific methods of study and teaching. Then came the division of subjects essentially distinct and the addition of new subjects. This growth led to specialism in practice, for which he had a good word saying, "Medical progress owes it more than can be imagined or expressed in words." The influence of examinations, the value of research by experiment, the increase of hospitals and other institutions, the development of medical literature and the opportunities for discussion in this and sister societies, and in recent times congresses, were among the means of the progress made. Dr. Roberts then proceeded to discuss the practical results attained. Of these he considered: (1) The improved position of the profession with its higher standard of knowledge and skill; (2) the extraordinary advance in positive knowledge of morbid processes and conditions, and the discrimination of diseases which had previously been confused together; (3) the light thrown on etiology and its results in prevention and hygiene, (4) the addition to our means of clinical investigation and diagnosis, culminating in the startling revelation of the Roentgen rays; (5) the advances in treatment, under which he referred to anæsthetics, antiseptics, hypodermic medication, and the remarkable triumphs of surgery.

After the presidential address there was a discussion on "Serum Therapeutics and Antitoxin Treatment," introduced by Dr. H. Heron, who took an encouraging view of the tuberculin treatment, and said he had never seen any untoward result, not even a superficial abscess, although at his hospital they had made above two thousand injections.

Dr. Washbourn thought it necessary to repeat that the two remedies differ, the antitoxins acting by neutralizing the toxins, the sera by preventing the growth of bacteria. He accepted Ehrlich's explanation of the action of toxins—that they combined with the tissues, and that antitoxins prevented this by themselves combining with the toxins. As antitoxin does not always succeed, he suggested that some tissues might have a stronger affinity for the toxins. He said that in all fatal cases the patients died with symptoms of paralysis of the vagus, and suggested that by preparing antitoxins from other animals it might be possible to obtain the remedy with an affinity for toxins more intense than for nerve tissue. With regard to antistreptococcic serum it sometimes succeeded and sometimes failed, and at present we cannot distinguish the cases. Antipneumococcic serum he thought deserved some further trial.

Dr. Hubbard had tried serum in two cases of aneurism as a coagulating agent. It had relieved the pain. He had used it also in menorrhagia with success, and further in a case of epistaxis in a hæmophilic patient it had succeeded after other plans failed. He could not satisfy himself that normal serum had equal coagulating properties. He thought the antidiphtheritic serum more effective than the others.

A conference called by the Hospital Reform Association was held on Tuesday and Wednesday. The attendance was not so large as was to be expected, to the regret of those who had energy enough to go and support the movement of the association. The subjects discussed were the inquiry system, payments by patients, provident dispensaries, and medical contract work. There was a programme which might have sufficed to attract a large number of ardent reformers as well as of those practitioners who suffer most from the abuses of hospitals.

Mr. Douglas Dent, of Bristol, spoke of the great increase of out-patients in that city, and held that proper inquiry was not difficult but easy, and would restrict charity to those for whom it was intended.

Sir William Broadbent admitted that he had seen at times patients who were not proper objects of charity, but thought it was not for the doctor to make inquiry or to protest. A proper inquiry officer should be attached to every hospital, and all should work on the same system.

Colonel Montefiore showed that many patients were admitted who could be far better treated in their own homes by general practitioners, and these are accordingly deprived of their practice.

Mr. Hawkins-Ambler, of Liverpool, said the general practitioners blamed the consultants, and these returned the compliment. He considered both to blame. An inquiry system would prevent fraud, and at the same time teach the public what hospitals were for.

Dr. Isambaud Owen believed that the rate of remuneration of the general practitioner had been reduced fifty per cent by hospital abuse.

Payments by patients was considered at the evening

meeting, and the levying of pence by the large hospitals was regarded with disfavor, though Mr. Holland defended the threepence charged at the London Hospital, which was not for advice but for medicine and appliances.

Mr. Timothy Holmes presided at the meeting devoted to provident dispensaries. This eminent surgeon has taken a great interest in these institutions from their first establishment. He said they enabled the poor to provide for themselves a family doctor. The hospitals, however, by their out-patient system compete improperly. Mr. Holmes has not been able to prevent this even at St. George's, of which he has been so long an ornament.

Mr. A. Smith said that in many cases the provident dispensaries were really sweating institutions — a number of people making a large sum out of the work of the doctors.

Sir W. Broadbent said the provident dispensaries might solve the problem if every practitioner in the neighborhood was allowed to share the work and the emolument.

## FAITH CURE.

To the Editor of the Medical Record.

Sir: In your issue of October 9th last, my attention was drawn to an article entitled, "Faith Cure and the Law." Now while I am a firm believer in the right of individual opinions, and my brother physician has certainly a right to his, as expressed in his article, I deem it no more than right that we of the profession who differ with him shall stand up in defence of our position, when we say that the laws regulating the practice of medicine ought to and should be enforced, and let the penalty be the same, whether the transgressor be a common quack or a Christian Scientist. Let it be a duty with us, one which we owe both to our profession and to mankind at large.

Without taking the time or space to go into a lengthy discussion of the Christian Scientist, let us look at the matter in a practical way and manner. Now for my part I do not believe in the theory of the Christian Scientist. I can see nothing in it—as I heard an old farmer put it, nothing which appeals to "good horse sense."

My experience with the Christian Scientist teaches me that abuse is his argument and ignorance his creed—ignorance, I mean, of the laws which govern all treatment for the relief and cure of disease. What citizen of this great republic would want a drug doctor to attend him in sickness, who could not tell pneumonia from gout, or the difference between the trachea and the œsophagus? I take it that such a person would be hard to find. No matter what the treatment, he demands a certain amount of knowledge.

To this we are told that no matter what the disease or number of diseases, the cure is all the same, providing the patient has a certain amount of faith and incidentally a certain amount of cash. If he recovers, well and good, and the details, carefully censored, are hurried abroad over the land. If he dies, he lacked the faith.

If faith be the only prerequisite, why the healer, who is often as far from the true religion as is a Tartar on his native steppe? Why the wandering professor, who professes to cure every and all forms of disease for one dollar—ever the almighty dollar, and all this in the name of the Deity? Does it not look like taking the name of God Almighty as an advertising medium? And who shall say that this is not worse even than using the folds of our starry banner?

We are shown a statement, and asked to believe it, viz., that the Christian Scientists cure as large a proportion of the sick as do drug doctors. I would like to ask, Where is the authority for such a statement? From whom does it come? Surely not from any member of our profession, and the Christian Scientist could not be authoritative for such a statement. He pretends to tell or boast of the number of diseases treated and cured, he who could not tell the foramen ovale from the carunculæ myrtiformes, and who would apply the same treatment to an attack of appendicitis as to a Colles' fracture. No, we do not believe it could come from him, and will do him justice, to say the least.

The law requires all who practise the art of healing to be graduates in medicine, and up to a certain standard any transgression of this law is punishable. And why should not this law be enforced in the case of the Christian Scientists? I would like to hear of one single reason. True, we are asked if we have no liberty in this matter, and can we not do as we choose? The same question might well be asked by the man who is made to desist from burning a pile of rubbish on his back lot, close to his neighbor's barn. In the first case you are endangering your neighbor's health, life, and the same of his family. In the second case it is his property, and you have no right to do either.

So the law should be enforced, and especially so when the life of an innocent child is at stake, who has no voice in the proceedings and goes down to its death at the bidding of one, while the thousands say no.

There are, I believe, none of us but who recognize to a certain extent at least the power of the mind over the body, and as a curative agent in disease. True, to make believe that a cure has been effected is equivalent to a cure itself is undoubtedly true in a great many cases, and alas, how many have come under my personal observation in which it was not true! But be this as it may, suffice it to say that whoever would practise medicine in this broad land of ours, be he Christian Scientist or other, let him conform with the law or stop.

When we look back over the past few years and note with pride the immense strides which our profession has taken, thousands of lives annually saved that were before lost, the many dreaded diseases utterly annihilated or now little feared, antisepsis with all that the word conveys, modern surgery, and the wonders that are now being done, and of which we read every day—I say, when we look back over all this we are not afraid (as we have been told) that our grandchildren will smile when they read of our absurdities, eccentricities, and contradictions, but think that they will commend us for defending our position, though in this case they may smile to think that we should have deemed even an argument in our behalf necessary. And by the aid of that which they will have learned from us, advancing far beyond where we are to-day, pushing the good work ever on.

When a Christian Scientist loses a case a great hue and cry is not raised against him because of it alone, but because the law has been violated. And in the case of the drug doctor, if he be a conscientious man nothing is said because his action was fully in accord with the law, and because a great majority of the people believe that everything has been done which could be done by the aid of skill, intelligence, and scientific research along the precepts laid down by Christ himself. Perhaps many a mortal at or near death's door who recovers does so by the direct will of God, but who dares to say that he is less likely to receive divine favor because he has tried to help himself, because he uses first every resource at his command to aid in saving the life which he loves, because he employs a drug doctor?

No believers in the true God doubt for a moment his power over all forms of disease and human suffer-

ing, but they do not believe that he will exercise his power when the subject of the affliction, by the use of his brain, his talent, the greatest of all God's gifts to man, may snatch the weapons for his defence from every meadow, wood, and glade, from the bowels of the earth, and from the very air itself, and meet his enemy as a man in the entire sense the term implies.

A. J. Richie, M.D.

Sylvania, Ohio.

## THE FILTHY WATER SUPPLY OF NEW YORK.

To the Editor of the Medical Record.

Sir: After something more than twelve years of absence I return to New York to make it once more my home, and find many surprising changes.

The time was, as old New Yorkers can recall, when the city's supply of water was so remarkably pure, that it was really a moral persuader and potent aid to the temperance movement. It was a delight to take a morning bath in a tub of pure Croton, but the believer in cleanliness thinks twice nowadays before he steps in a bath of light-brown colored liquid from which he emerges mulatto-colored. Instead of the song of the "Old Oaken Bucket," one can very properly say:

"The typhoid old bucket,
The bacteria-filled bucket,
The germ-diseased bucket.
We all know so well."

In the thousands of flat houses in New York the tenants are depending on the water that is stored very largely in roof tanks, and what sometimes comes from the faucets is an unending source of surprise to the occupants of the houses—brown mud, gravel, wisps of straw, small worms, diminutive tadpoles, and other like trifles, but, seriously speaking, the state of affairs is very bad all over the city, as every one knows.

There is no place now, within the limits of Greater New York, as near as I can learn from careful inquiry, where pure water, or anything like pure water, can be had from the public supply. The quality and quantity of the water during the past summer have been matters of serious and constant complaint, because of its utter unfitness for domestic use, either for bath, cooking, or drinking. The water department of this city has been flooded with complaints. If they were made public there would be an uprising of the citizens, and during this past season the rate of infant mortality under five years of age has risen from 9.1 per cent. average for the balance of the year, to over thirty per cent.

There were reported for the first five days of last July one hundred and twelve deaths among children in New York City proper from diarrhœa alone.

The reports of analyses made by the health department show that the albuminoid ammonia in the samples of water during this week is almost double what it was in the comparative reports of 1897 and 1898. This shows that the water is polluted by decayed vegetable matter, sewage, or other poisonous material. In addition to this cause of the bad state of the water, there is growth in the old water mains of fungus, accumulation of slime and other things, resulting from stagnation because of the low pressure. These reports also show a minute percentage of nitrogen, the significance of which has a most vital import in the increased death rate.

The condition of the water supply in the new and fashionable West Side district, between Seventy-second and One Hundred and Twenty-fifth streets, has called forth public remonstrances in the neighborhood from a number of the best-known physicians in this district. The pressure is so low that the residents must depend for their drinking-water during the day upon the supply that fills the tanks during the night when the water can mount to the height where they are located. In the three- and four-story private houses the supply-tank is usually on the top floor in the room usually denominated the "trunk" room. The top, as a rule, is boarded over, ostensibly to keep out the dust, but the cover finds general use as a shelf on which to store light articles. There is an automatic valve by which the supply is cut off when the tank is full, and a stop-cock in the supply pipe and one in the feed pipe. The top of the feed pipe projects upward from the bottom of the tank, perhaps two inches, to keep the sediment out. Trusting solely to this precaution, and more often because of ignorance of the fact that the family derives any water supply from these tanks, the larger number of householders neglect them for years. However, this class, in this fashionable section, when they find the water unfit for use, can purchase distilled water at their chemists at the rate of five gallons for fifty cents; but what about the tenement districts, which, as we know, are more largely supplied by the tank system than others? Out of two hundred and fifty-one of these tanks examined by the health board, one hundred and fifteen were found to be in an unhealthful condition. It goes without saying that neglect of these receptacles is one of the most frequent causes of disease, and it amounts to a criminal omission of duty by the owners which the law ought to ferret out and punish unsparingly, that our health board does not look to it that this particular source of water supply is not regularly inspected and kept in a sanitary condition.

I have mentioned that five one-gallon bottles of distilled water are sold for fifty cents, by the single bottle the price is twenty cents, and herein the city authorities trade upon the poverty of their inhabitants, for the poor and wretched can ill afford to buy five bottles of pure water at a time, and must be content with a single bottle at the double price when ordered by the doctor.

While we hear talked of and see constantly in the daily papers the projected expenditure of hundreds of millions of the public moneys for the increase of rapid transit, for the repaving of streets, and for public improvements innumerable, there is too little agitation as to the preservation of the lives of the people who are expected to enjoy these improvements, by furnishing to them an adequate and healthful supply of water.

While the craze for public improvement is so rampant, why should not the corps of physicians, who by natural right are the guardians of the public health, make a demand upon our city fathers that they shall give us something besides rank poison to quench the thirst of our city's children?

If it is necessary, we can go back to the Roman Empire and learn some lessons from their extensive aqueduct systems, of their high appreciation of the necessity for a sufficient supply of pure water.

P. Sherwood-Dunn, M.D.

New York, October 28, 1899.

**The Detection of Strychnine in Bodies Long Buried.**—Dr. Haw reports in *The Lancet*, September 23, 1899, the case of a man previously in good health and supposed to have taken strychnine with a fatal result, "in which, when exhumation was practised for medico-legal purposes after the lapse of nearly ten months, the body was found still in a state of fairly good preservation, and $\frac{1}{2}\frac{1}{0}$ mgm. of strychnine was obtained on chemical analysis from the stomach, intestines, liver, remains of the spleen, the left kidney, the spinal cord, and fluid from the thoracic and abdominal cavities."

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 28, 1899:

| | Cases | Deaths. |
|---|---|---|
| Tuberculosis | 151 | 140 |
| Typhoid fever | 75 | 20 |
| Scarlet fever | 117 | 4 |
| Smallpox | 4 | 0 |
| Measles | 176 | 8 |
| Diphtheria | 206 | 29 |
| Laryngeal diphtheria (croup) | 13 | 8 |
| Cerebro-spinal meningitis | 0 | 6 |
| Chicken-pox | 18 | 0 |

**Pyuria with an Acid Urine,** especially if intermittent in character, at once calls attention to a strong probability of renal tuberculosis. Again, a spontaneous and intractable cystitis should always be regarded in the same light as a spontaneous bronchitis—an indication of a tuberculous process.—VANDERVEER and MCDONALD.

**War Echoes.**—In reviewing the war correspondence of Dr. Senn, the *British Medical Journal* of September 2d says in regard to the examination of recruits: "We suspect many bad bargains must have slipped through who at the end of the war probably further swelled the gigantic American pension list, by diseases supposed to have been 'contracted in and by service'!" And in speaking of the recruiting, ranking, etc, the following complimentary words are used: "Such a condition of things is almost incredible, and the wonder is, not that there was confusion and constant breakdowns, but that anything was accomplished at all Truly the patriotism, versatility, and practical ability of the American people must be unbounded to make headway against such a system."

**Rate of Nail Growth.**—A considerable divergence of opinion exists as to the rate at which the finger-nails grow. Bean gives as a rule that the nails of the hand grow 1 mm. per week. At this rate the nails, which average 15 mm. in length, would take one hundred and five days to grow out. Dufour gives one hundred and twenty-one to one hundred and thirty eight days. The fact is, the pace of growth varies very much, not only at different ages, but in different individuals of the same age. Influenced by many external and internal conditions, the pace also varies in the same person from time to time A few observations will be submitted to the notice of the reader as to the growth of finger-nails in men at different ages. At twenty-one years the nail was replaced in one hundred and twenty-six days, at thirty-one years in one hundred and fifty-nine days; at thirty-two years in eighty-eight days, at fifty-five years in one hundred and ten days; at sixty-seven years in one hundred and forty-four days. It is curious that in this growth the swiftest grower was a tuberculous subject who had a sharp attack of blood-spitting during the observation. Sea air is said to quicken the growth of the nails, profound grief has been credited with the power of destroying them. A valuable point of diagnosis is afforded by the growth of the finger-nail. In distinguishing between true paralysis of centric origin and the various pseudo-paralyses of hysteria which sometimes so closely simulate organic disease, it is well to remember that the growth of the nail is modified by most of the centric lesions, while its development is not affected by hysteria. It is asserted that intracranial hemorrhages arrest the nail growth.—EDWARD BLAKE, "Study of the Hand."

**Vital Statistics in the United States.**—The fact has long been recognized that the adoption of a uniform certificate for the return of deaths would greatly simplify the work of those whose duty it is to prepare the census tables. The chief statistician of vital statistics in this country is at present engaged in the endeavor to bring about this result, and to establish a common national system of collecting vital statistics. That this object cannot be successfully accomplished without the co operation of the physicians in the various States is fully appreciated, and therefore an earnest appeal is made to the members of the medical profession to lend their assistance. The MEDICAL RECORD has on more than one occasion drawn attention to the defective working of the existing methods of collecting vital statistics, and has urged the introduction of reforms. The following condensed statement of facts has been issued by the census office: "Correspondence has been had by the chief statistician, Mr. William A. King, with the officers in charge of mortality registration in the States employing a uniform system, and in the cities having a population of five thousand and more at the last census, which also collect and register death returns. Complete and accurate information of the different methods in vogue has been obtained, and it was found that there is much unnecessary and objectionable variation, considered from the census point of view, in the form of official returns Having no power to compel co-operative action, and hampered by want of time in which to carry out the whole project, nevertheless the census office undertook to secure the modification or amplification of the death certificates so as to have them include the items necessary to obtain census data. A model return form was prepared and submitted with explanatory correspondence to each registration office or officer controlling the preparation of the State or local forms. The result has been more important and gratifying than even the census office expected, as not only have the items in the specimen form been very generally adopted, but the registration officers have abolished many practically obsolete local variations in their certificates, and the latter have been made to conform to one standard more nearly than ever before. The promptness and willingness displayed by the State and local officers in complying with the request of the director have been surprising as well as gratifying. The benefit that will result to the census office and to science from this first step toward the goal of national uniformity is incalculable, but it will be seen readily that the study of the natural law of the growth of population is made easier and more certain. The director of the census confidently expects that physicians everywhere will appreciate the desirability of the new order of things, and that they will earnestly and actively cooperate in securing prompt and accurate mortality returns of the uniform character required by Congress and sought for by statisticians. He recognizes the fact that failure on the part of physicians to give vitality to the common standard by carefully reporting the items that may be new to their certificate may be fatal to the end in view."

**The Electrotherm Compress** is an apparatus devised by Lindemann (*Berliner klinische Wochenschrift*, September 18, 1899) for making applications of heat to the body by means of an electric current passed through resistance wires carefully covered by asbestos and flannel. Special designs are constructed for different parts of the body, and any desired amount of current can be obtained by means of a rheostat, and any degree of temperature can be attained and main-

tained for any given length of time. The apparatus is dry, clean, neat, regulable, and time-saving. It may be employed in the same way as a dry-heat apparatus. Apart from its direct application it may be employed to heat cataplasms, when these are deemed ncessary. It may be fitted out as a pillow for the neck or for the abdomen, or in the form of a semicircle for the knee, the elbow, or the shoulder, and in the form of a sheet to be placed upon the mattress to supply warmth or to induce sweating. The same principle may be applied further to warming articles of food, as, for instance, milk for children or invalids, at night.

**Soda-Water to Relieve Hunger.**—According to *Modern Medicine*, soda-water is now prescribed as a palliative for hunger, especially for the abnormal hunger produced by disease. The above-named journal says: "Carbonic acid gas has the singular property of lessening the sense of hunger, and may profitably be remembered in dealing with cases of diabetes in which bulimia is a prominent symptom. The seat of hunger is found in the solar plexus. By the use of water charged with carbonic acid gas the branches of the solar plexus distributed through the mucous membrane of the stomach are influenced in such a way that the abnormal irritation of the plexus which is the foundation for the ravenous hunger often present in diabetes and certain forms of indigestion may be greatly mitigated, if not wholly appeased. Water charged with carbonic acid gas may likewise be employed with advantage in many cases of hyperpepsia in which there is a sensation present in the stomach described by the patient as a gnawing 'goneness,' emptiness, etc."

**Should Physicians Tell the Truth to Their Patients, when Suffering from an Incurable Malady?**—The law lays down the dictum emphatically that physicians should use the utmost good faith toward their patients, but a reported Missouri decision carries this doctrine to unconscionable lengths. This decision was to the effect that if the doctor is aware that the patient is past cure, or that his treatment will probably be of no benefit, "it is his duty to advise his patient of these facts, and if he fails to do so he is guilty of a breach of trust." In many instances such a declaration would have a disastrous effect upon the sufferer, but this view of the situation is altogether ignored. These matters are better left to the discretion of the physician.

**The Biter Bit.**—The following amusing tale was recently told to his class by Professor Comstock, of Cornell, in speaking of the trials of scientists. It appears that a professor of invertebrate zoölogy in a sister university wished to procure some trichinous pork for purposes of experiment. The learned scientist went to his butcher and asked him if he ever got any measly pork. "Sometimes," the butcher cautiously answered, "but I always throw it away." "Well," said the professor, "the next time you have any I wish you'd send me up some," meaning, of course, to his laboratory. The butcher, although somewhat taken aback, said that he would. Three weeks passed, when the professor, growing impatient, again visited the store. "Haven't you found any measly pork yet?" "Why, yes," said the butcher, "I sent up two pounds a week ago." A sickly grin broke over the professor's face. "Where did you send it?" "Why, to your house, of course," said the butcher.

**Infectivity of Milk from Tuberculous Cattle.**—While the observations of the majority of those who have interested themselves in this matter leave no doubt as to the infectivity of milk from cows affected with either generalized tuberculosis or with local tuberculous disease of the udder, there has been some difference of opinion as to the danger attending the use of milk from cattle affected with other and lesser degrees of tuberculosis. Lydia Rabinowitsch and Kempner have recently investigated this latter question. The milk from fifteen cows which had reacted with tuberculin was examined, and the presence of tuberculosis bacilli was proved in the milk of ten, or about sixty-six per cent., by means of animal inoculations. Of these ten cows nine showed, save for the tuberculin reaction, no clinical evidence whatever of tuberculosis. In two of the animals the post-mortem examination showed no obvious tuberculous lesion, in spite of the proof afforded by the inoculation experiments that their milk had contained tubercle bacilli. In these two cows the tuberculosis is described as being "latent"; but it is obvious that a very careful examination of all the bones would have to be made before the use of the term could be strictly justified.—*English Public Health.*

**John C. Whittier's Color Blindness.**—The Boston *Transcript* prints a letter from Robert L. Rantoul to the Whittier Club, in which he said: "Mr. Whittier told me the story of discovering his color-blindness when his mother had taken him out to pick wild strawberries and he could find none. He told me of the embarrassment this limitation had caused him through life lest, in describing flowers so freely as he had done in his poems, he might sometimes go wrong as to the coloring."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 27, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |
| Massachusetts, Butler | September 30th to October 18th. | 2 | 1 |
| Everett | October 14th to 21st | 1 | |
| Michigan, Saginaw | October 14th to 21st | * | |
| Montana, Butte | September 30th to October 18th. | 2 | 1 |
| New York, New York | October 14th to 21st | 3 | |
| Ohio, Cleveland | October 14th to 21st | .. | 5 |
| Texas, Galveston | October 20th | 1 | |
| Virginia, Alexandria | October 20th | 1 | |
| Portsmouth | October 19th | 1 | |
| * Present in five places. | | | |
| **Yellow Fever—United States.** | | | |
| Florida, Key West | October 16th to 27th | 61 | 4 |
| Miami | October 23d to 26th | 12 | |
| Louisiana, New Orleans | October 21st to 25th | 7 | 2 |

### TEN YEARS' EXPERIENCE WITH TYPHOID FEVER AT THE ROOSEVELT HOSPITAL.

By W. H. THOMSON, M.D., LL.D.,

NEW YORK,

PHYSICIAN TO THE HOSPITAL.

THE observations which I propose to make on this occasion are based exclusively on my own experience with typhoid fever for the past ten years, from September 1, 1889, to September 1, 1899, in the wards of the Roosevelt Hospital during the months of my service. Those months were June, which according to the health-board statistics corresponds to the time of least prevalence of this fever in New York, and September and October, which correspond to the time of its greatest prevalence. I wish here to express my thanks to Dr. Ernest V. Hubbard for the work done in collating the statistics from the hospital records.

Owing to its gradual development and prolonged, though fairly definite course, this fever offers better opportunities than almost any other acute disease for noting whether we can modify in any way its natural course so as to lessen its dangers or complications.

In a paper read last November before the Harveian Society by Dr. Sydney Phillips, physician to the London Fever Hospital, he maintains that while typhoid fever during recent years appears to have changed its type in the lessened severity of the accompanying abdominal and nervous symptoms, yet according to English statistics the fatality from the disease has not altered, so that the chances of recovery of a person contracting typhoid fever to-day are little or no better than they were fifty years ago, notwithstanding the advances in medical knowledge and improved nursing and hygienic conditions. Murchison found that the mortality of patients in the London Fever Hospital during the ten years ending 1862 was 18.5, and Dr. Phillips says that all the figures available to him in the same fever hospital and other metropolitan institutions, as well as the registrar-general's returns, show that the mortality from 1890 to 1897 still remained over eighteen per cent.

Notwithstanding the recognition of Dr. Phillips that many of the symptoms of typhoid fever seem to be less severe at present than they were formerly, but, as he claims, without showing any improvement in the chances of recovery, I cannot but feel that a comparison of the clinical features of the cases with the picture given by medical writers thirty-five years ago, as in the works of Watson and of Bristowe, will have some bearing upon the question whether we have made any advances in treatment and that such a clinical comparison does offer more trustworthy data than the mere percentage of death rates. Because if methods or measures of treatment have any influence in modifying the course of such a long-continued fever as typhoid, they cannot do so at once in any stage of the disease, but rather in proportion to their being begun early in its course. Now it happens that hospital experience is often imperfect in this very particular, because only a minority of the patients are admitted at the inception of the fever, while most are not admitted until it is well advanced into the second week, and very many not until they have been twenty-one days sick. The effect of this fact upon the death rate itself is shown in my own experience as follows:

Whole number of typhoid-fever patients treated by me at the Roosevelt Hospital from September, 1889, to September, 1899, 368; males, 275; females, 93. Whole number of deaths, 25, or 6.8 per cent. Of these 19 were males and 6 females. Of those who died, however, 56 per cent., 8 males and 6 females, 14 in all, died within a week after admission. How far they were advanced in the fever may be judged from the fact that the average duration of the fever before admission for the whole 368 was 9.43 days. Many of them who died in the first week were in a hopeless state, if not actually moribund, on their reception. Among the 93 females there were no deaths after the first week following their admission, that is, in 87 of the 93. If, therefore, we counted those only who died after they had been a week or more in the hospital under treatment, they would number 11, or only 3 per cent. As the London hospitals, however, presumably report their entire death rate, our figures of 6.8 per cent. is to be offset against 18 per cent. in London.

But, as already remarked, the proportion of occurrence of the leading symptoms characteristic of this disease and their severity, as far as they can be derived from the clinical histories, furnishes a better criterion of the efficacy, or the reverse, of any methods of treatment than the mere percentage of deaths or of recoveries. Following, therefore, Bristowe's enumeration of symptoms, the first which we would advert to is diarrhœa. He speaks of it as generally associated with the initial symptoms, though sometimes absent then, to become, however, a striking feature of the disease and rarely absent from the second week on. He deprecates on this account the use of laxatives, unless perhaps a small dose of rhubarb or of castor oil during the first week, and he regards the recommendations of Trousseau and of George Johnson, that the diarrhœa should be allowed to run its course, as erroneous and dangerous, preferring to check it by the systematic administration of tannic acid, sulphuric acid, lead and opium, etc. In my own records, diarrhœa occurring after the first week following admission is reported in only thirty-two out of the three hundred and sixty-eight, or 8.7 per cent., and in the majority of them it was not severe, so that there are very few prescriptions recorded as administered specially for this symptom. On the contrary, constipation which had to be relieved by enemata was of very frequent occurrence, but the percentage unfortunately has not been made out. The absence of diarrhœa in typhoid fever is not confined to my own hospital experience, but has been reported of late years as common in American hospitals generally, and is noted, though to a less extent, in the English reports. I would ascribe this change in large measure to a change in the feeding of fever patients. Thirty years ago the use of beef tea in typhoid fever was almost universal. I believe that hardly any articles are so prone to fermentation in the alimentary canal, and to induce tympanites, as the continuous ad-

ministration, day and night, of meat broths in febrile conditions. Tympanites thirty years ago was so constant a symptom that it was rated as a diagnostic feature of the disease. As Watson says, "if you make pressure on the abdomen you will find it unnaturally hard and resisting, as though its walls were much distended; but, whether large or not, Dr. Jenner states that its shape is invariably the same and peculiar. The patient is never pot-bellied, but tub-shaped."

As I have always placed a good deal of store upon this symptom, I have had its occurrence noted in every case, with the result that even its temporary presence was not overlooked. So infrequently had it been a marked symptom, according to my recollection, in any but the fatal cases, that I was surprised to find that it had been recorded as present in eighty-four patients, or 20.2 per cent. On reviewing this record, however, it was found that nearly one-half the whole number of instances of tympanites occurred in September and October, 1898, and was noted in thirty-nine soldiers admitted for typhoid fever contracted at various camps in our own country and in Cuba. Of these, six had also a mixed infection of typhoid fever and of malaria, in four of whom the plasmodium malariæ permanently disappeared after the typhoid fever ran its course, while in two others chills and fever, with a reappearance of the plasmodium in the blood, took place after they had fairly convalesced from typhoid. It was probably owing to the reduced constitutional condition of these soldiers from the poor food and other hardships of camp life that they so generally presented this symptom on admission. Deducting, therefore, these soldiers, the occurrence of tympanites at all is recorded in only about forty-five patients, or about eleven per cent. at most. Its presence in the records is generally in those who were admitted late in the disease, and in the majority of them it disappeared soon afterward under treatment. The prevention of this particular symptom I believe to be not without bearing upon the question whether we can favorably modify the course of the fever, for tympanites is both a sign and a complication. It is a sign of weakened innervation and of loss of normal antiseptic power in the gastro-intestinal secretions on the one hand, and a direct cause of cardiac and of pulmonary enfeeblement on the other, while it cannot be without some effect in increasing the tendency to accidents at the seats of intestinal ulceration. I always regard a persistent tympanites in a typhoid patient with uneasiness, and any method of treatment in which this symptom becomes a rarity I cannot but consider as materially beneficial.

The number of patients in whom hemorrhage from the bowels occurred was twenty-seven, or 7.3 per cent. In no instance was it directly fatal. When the bleeding was very profuse the hypodermic injection of ℥ viii. to xii. of decinormal saline solution, ℥ i. to O i. sterilized water, was markedly beneficial. The best site for this hypodermoclysis is in the lumbar region between the crest of the ilium and the twelfth rib. At this site no pain will follow upon any muscular movement of the patient. The temperature of the water should be about 110° F. An ordinary hypodermic needle may be used, attached to a fountain syringe.

Among the nineteen deaths of male patients, four succumbed to intestinal perforation. Two of these occurred among the soldiers admitted in 1898, and while they were convalescing. It was noteworthy that both of them had refused to enter their camp hospitals for a number of days after they were ill with the fever, and they continued to report for marching duty when they should have been in bed. In both of them laparotomy was performed by my colleague Dr. Robert Abbe as soon as possible after they showed symptoms of this accident, but to no avail, one dying on the day of the operation, while the other survived it five days.

To continue our comparison with the English experience: Dr. Bristowe proceeds to describe "the typhoid condition" into which he states that a large proportion of the cases pass in the second week. "The elevation of temperature continues, the rash still comes out, the diarrhœa still persists; the tongue becomes dry and brown and traversed by deep fissures; the lips and teeth are covered with sordes; the mind grows dull and apathetic; and delirium, sometimes violent, sometimes busy, sometimes muttering, supervenes: bed sores tend to form; tremors, subsultus, and involuntary passage of the evacuations take place," etc.

I may say that as a whole this picture is one of great rarity in my experience. Thus as to a delirium, it was noted in forty-seven, or 12.7 per cent. But of these fifteen, or thirty-two per cent. of them, were delirious on admission, four of whom died within that week, while the rest recovered from their delirium in a week or less. The total absence of delirium in the remaining three hundred and twenty-one patients, or 87.3 per cent. of the whole number, is at least an indication that they hardly passed into the typhoid condition pictured above at any time in the course of the disease. Some of them were drowsy, but tremors and subsultus were too rarely observed to figure among the clinical symptoms. The state of the tongue was always carefully noted, but fissures in it were not once recorded. Sordes on the lips and teeth were present in patients on admission, but in every case soon cleared up, and never were recorded as developing in patients after admission. Of this fact I feel quite sure, for it has seemed to me that a remedy to be mentioned soon is commonly quite efficacious in preventing general dryness of the tongue if administered at the first appearance of this symptom at the tip.

Of other complications in our series, pneumonia occurred in ten, or 2.7 per cent; bronchitis in twenty-nine or nearly eight per cent., but it was an initial symptom in more than forty per cent. of them, and was easily controlled.

Peripheral neuritis occurred in twenty-four, or not quite seven per cent., of the cases, and in each case was limited to the feet. The causation of this symptom in typhoid is apparently purely mechanical from the foot-drop induced by prolonged relaxation of the leg muscles. The peripheral neuritis of phthisis is probably partly, though not wholly, due to the same condition.

Phlebitis occurred in seven. In two of them it was very troublesome and much prolonged the convalescence.

Subcutaneous abscesses occurred in twenty-nine, or nearly eight per cent. This large number, however, for such a complication, occurred mainly in the form of a furuncular epidemic in the autumn of 1894 and 1895, in patients who took a large number of baths, while they rarely appeared in those who took but few baths. I learned that during those years a similar experience was encountered in other hospitals in this city, and I myself had the same proportion of such cases in the typhoid-fever patients in my wards at the Bellevue Hospital. I ascribed it then to the presence of an infectious organism in the Croton water. It constituted a serious complication, greatly retarding recovery, and in two cases it seemed to contribute to a fatal result.

Relapses occurred in fifty-five, or in no less than fifteen per cent. of all the cases; though some of them seemed to occur in near sequence to some imprudence in eating articles surreptitiously furnished by friends during the hungry period of beginning convalescence, yet in most instances no such cause could be assigned. Moreover, the tendency to relapses is much more marked in some years than in others, rising as high as thirty per cent. of all cases in one year, so that the eti-

ology of these recrudescences of this fever must be regarded as obscure. In London also it is noted that the three per cent. of relapses given by Murchison has now risen to thirteen per cent. As a rule the prognosis is not unfavorable except in those cases which begin the relapse with vomiting.

In one of the fatal cases (male) typhoid ulcers were found only in the large intestine, where they were very numerous. One case, of a man aged forty years, five years ago, ran through a course of typical typhoid fever clinically, but after he had so far convalesced as to be allowed to begin taking solid food he developed an abdominal pain and fever of a septic type, and died in ten days. At the autopsy extensive pelvic myositis was found, but no evidence was discernible of any antecedent ulceration whatever in the intestine or in the appendix. I greatly regret that no cultures were made from the pelvic exudate, for I have no doubt that his was a case of typhoid fever without implication of Peyer's patches.

My method of treatment of typhoid fever has been as follows: On admission, if at any time before the end of the second week, a mercurial purge of gr. v. of calomel and gr. xxxv. of compound jalap powder is administered, and this purgative is repeated every third night till the close of the second week. The presence of diarrhœa is no contraindication to its administration, for rather it seems to check it altogether, and to change the character of the movements in the majority of cases. It seems directly to lower the temperature as its first effect, and to moisten the tongue. My belief is decided that a mercurial cathartic acts as an effective gastro-intestinal antiseptic, and lessens the toxæmia. In many cases I have continued it well into the third week, ceasing its administration only when there was cause to fear the supervention of intestinal hemorrhage.

The exclusive diet until the fourth week is equal parts of milk and lime-water. Such a dilution of the milk, I think, is imperative, for the majority of even healthy adults cannot take large quantities of fresh milk continuously without inducing digestive disturbances, as is proven on a large scale by the invariable practice of all pastoral peoples, who have to live largely on milk, of fermenting the milk first so as to spare the stomach the preliminary task of curdling it. I prefer lime-water as the diluent on account of its decided antiseptic properties. In the fourth week, farinaceous gruels, preferably arrow-root, is added.

As typhoid fever has been shown to reduce the peptic secretions of the stomach more than any known disease, not excepting gastric cancer, I see no reason why we should not attempt to supplement the deficiency by administering pepsin. The theoretical objections adduced by some physiologists to pepsin preparations as both insufficient and inert, I reject altogether. In typhoid fever the stomach is reduced to the weakness of early infancy in digestive power; hence I would not give milk undiluted. But practically I have repeatedly seen, especially in consultation practice, gastric tympany speedily subside on the administration of pepsin. From the beginning to the end of the fever, gr. x. of pepsin and gr. x. of bismuth subcarbonate is ordered by me every three hours, so as to amount to gr. lxxx. of each in the twenty-four hours. In many cases the dose of bismuth is gr. xx. Bismuth I regard as much our most serviceable intestinal antiseptic, and experience leads me only to increasing rather than to decreasing doses of it. With this medicinal management of the alimentary canal not only are the tendency to dry tongue, stomatitis, pharyngitis, parotitis, otitis (I have never had a case of typhoid ulceration of the larynx in my wards), and diarrhœa notable by their absence, but the emaciation of this fever is equally prevented, in marked contrast to what I have witnessed in patients who had been otherwise treated. As soon as the tip of the tongue shows the first sign of dryness, ℥x.–xx. of spiritus terebinthinæ are given every four hours in emulsion.

This constitutes the stated medication of the case, for the indications presented by signs of circulatory weakness are met as they arise by the ordinary resources to alcoholic and other cardiac stimulants, with the exception of digitalis. To check intestinal hemorrhage, gr. ¼ of silver nitrate and gr ¼ of opium are enveloped, so to speak, in gr. ix. of resin of turpentine in three pills, and this dose is given every two to four hours. These pills are so slowly dissolved in the intestine that some may pass unacted upon, in which case ℥v. of liquor potassæ should be added.

Against the general toxæmia of typhoid fever there is in my opinion no measure which approaches the cold bath. I have had recourse to it in every case of typhoid fever under my treatment since the year 1874, and I order the patients to be put at once into the tub as soon as the temperature reaches 103° F. Active friction of the whole body is kept up by the attendants while the patient is in the water, and ℥i. of Hoffman's anodyne in camphor water is given as soon as he is taken out, to shorten the subsequent shivering In some weak patients this is also given before the bath. I think that the observation, now fully confirmed, that the cold bath doubles the toxicity of the urine, points to the eliminative action of this measure as a more likely explanation of its life-saving efficacy than its mere antipyretic effect. During my service in 1889, I had every other patient given their baths charged with the artificial Nauheim salts and carbonic acid. In comparison with patients treated with ordinary cold water, the depression following the Nauheim baths was undoubtedly less, while the antipyretic effect was more prolonged, probably from the general cutaneous stimulation of the salts and carbonic acid. On the account I have since freely recommended this modification in consulting-practice. The addition of a pound of common sodium carbonate to the Nauheim bath increases the effect.

Owing to my routine practice now to treat every case of nephritis with oliguria by rectal irrigations of from four to six gallons of decinormal saline solution, administered by Kemp's rectal irrigator, this measure is always adopted at the hospital in every case of typhoid fever with albuminuria, but I would recommend it also in all cases of this fever with severe toxic symptoms, on account of its effect in promoting renal elimination.

## ELECTRICITY IN RESPIRATORY AND CARDIAC FAILURE, WITH A CASE OF PARALYSIS OF THE DIAPHRAGM.[1]

By A. D. ROCKWELL, M.D.,
NEW YORK.

Duchenne was, I believe, the first to demonstrate that the diaphragm, notwithstanding its supreme importance in the act of respiration, might be completely paralyzed with no fatal results, if uncomplicated with any serious pulmonary attack. Sudden death may indeed follow paralysis of the diaphragm, but in such a case there must also be coincident paralysis of the intercostal and other auxiliary muscles of respiration.

As Luschka has shown, the diaphragm possesses a double innervation: first, a principal and fundamental innervation furnished by the phrenic nerve; second, an accessory innervation, the source of which is in the last intercostal nerves. It is only through disease or injury of the spinal cord above the origin of

[1] Read before the American Electro-Therapeutic Association, September 19, 1899.

the third and fourth cervical nerves that all the muscles concerned in respiration are paralyzed. Disease of the phrenic nerve below its junction with the cervical nerves permits respiration without seeming effort notwithstanding the paralyzed diaphragm, so long as the patient remains quiescent. It is only when muscular effort is attempted that the breathing becomes greatly embarrassed.

The following case not only illustrates these statements and the value of electric excitation of the phrenic nerve, but is a fitting preliminary to a discussion of its relation to respiratory and cardiac failure.

John B——, a musician, aged thirty-eight years, consulted me on January 9, 1899, for a generally depressed vitality, and especially for an inability to "breathe properly," as he expressed it. Some three months before he had had an attack of la grippe, but of so slight a character as not to prevent his playing each night with the orchestra of which he was a part. The attack persisted for several weeks with increasing respiratory oppression, until finally he was compelled to abandon altogether the wind instrument which he played. He grew gradually worse, and when I saw him the effort of walking tasked his respiration greatly, while to ascend the stairs was an impossibility without two or three halts on the way. He suffered from transient aphonia, *i.e.*, after exertion he could with difficulty articulate, and his utterance would be in a whisper. As the dyspnœa subsided the voice grew stronger and became natural. His pulse was 68, and when in repose, sitting or reclining, his respiration seemed neither hurried nor unnatural, but its unusual frequency, 28 per minute, was readily detected by placing the hands on either side over the ribs, when the quick costal breathing was very apparent. An inspection of the bare chest and trunk revealed very distinctly the essential characteristics of paralysis of the diaphragm. When the patient was directed to attempt deep inspiration and to breathe rapidly, the epigastrium, instead of becoming more prominent, was depressed, with a distinct line of demarcation between the chest and abdominal cavity. During expiration, however, the epigastrium became full, instead of sinking as is the case in normal respiration.

An application of the faradic current to the phrenic nerve, one pole (the positive) at the outer border of the sternocleido just above the clavicle, resulted in a deeper inspiration and a very slight though appreciable bulging of the epigastrium. This treatment was repeated every day for one week, and after every séance the patient expressed himself as having experienced a certain sense of well-being, greater freedom in breathing, and a capacity for increased physical exertion. At the seventh visit I substituted for the faradic current the combined currents, or galvano-faradization.

If in your own person you will make a comparative trial of either the faradic or galvanic currents alone, and then the two currents in combination, you will be not at all surprised, if your experience is the same as mine, at the following statement as regards the effect of the latter method on my patient. Whereas by the use of either of the two currents alone there resulted only a comparatively slight bulging of the epigastrium, the currents in combination caused a greatly increased prominence both of the epigastrium and the hypochondria. It was very evident that this combination of mechanical and chemical effects stimulated the phrenic nerve more powerfully than either current alone. Even after the first application of the combined currents there resulted an ease of respiration not before experienced, and that did not altogether subside in the twenty-four hours elapsing before the next application. From this time the patient improved gradually but surely, and within a month regarded himself as again quite well.

The action of electricity on the pneumogastric and phrenic nerves is one of very considerable importance, and one, too, about which there has been more or less misapprehension. It is a very easy matter to influence the respiration through the phrenic nerve, but more difficult to illustrate its control over the action of the heart through the pneumogastric. Experiments on animals have, however, demonstrated this power very clearly, and I have in man witnessed several striking illustrations of its action, notably so in a case of cancer of the breast under treatment by electrolysis. The tumor had been removed with the knife, and the exposed tissue was subjected to the electrolytic action of a powerful current, resulting in an immediate and profound effect on the heart's action. Its beat became for the moment not perceptibly weaker, but alarmingly slow. On discontinuing the current the pulsation immediately became normal, only to slow up again on reapplying it. Thus we see that stimulation of the pneumogastric, either in physiological experiment or in the course of a surgical procedure, calls into increased activity the inhibitory function of this nerve, slows the action of the heart, and carried beyond a certain point may arrest its action altogether. Stimulation of the phrenic nerve, on the contrary, is followed by quite different effects on the great muscle which it supplies. A successful electrization of the phrenic nerve results in a marked increase in the activity of the diaphragm. The inspiration becomes deeper and stronger, the epigastrium bulges, and the contractions of the diaphragm can even be felt by pressing the hands firmly over the sides. Basing opinion solely on the results of physiological experiment and observation in surgical cases, the conclusion is not unnatural that while in respiratory failure electrization is of value, in cardiac failure this method is not only inefficacious, but may even endanger life. It is unnecessary then to dwell further on the benefit to be derived from electricity in respiratory failure. Whether it be threatening death from opium, aconite, or drowning, experience abundantly attests its value, and no one disputes it. A question here arises as to the relative merits of artificial respiration and electrization. It has been claimed that artificial respiration answers all the purposes of electrization in cases of opium poisoning, for example, besides being always and instantly available.

Unfortunately this simple and most valuable procedure would certainly fail in some cases in which the other succeeds. I can recall two cases of opium poisoning out of a number thus treated, in which life was saved by keeping up the respiration for many hours until the effects of the poison began to wear away and the phrenic nerve again resumed its function.

It is exceedingly doubtful if artificial respiration could succeed in such cases. In one case of this kind in which I continued the application for eight hours its remarkable effects were strikingly manifested. When found the patient was so profoundly narcotized that the respiration had fallen to five a minute. Stimulation of the phrenic nerve raised it to ten. After two hours of uninterrupted treatment it had sunk to eight, and if the application was suspended for a moment it fell to about three, showing that the full narcotic effect had not been reached when the treatment was begun. Immediately on resuming the current, the respiration would get up again to eight, and as the effects of the opium gradually wore away the frequency of the respiratory act increased until it reached its normal rate, and the patient was saved.

Now is it true that electrization, while of value in respiratory failure, is useless or even harmful in cardiac failure, more particularly when due to chloroform narcosis? To this question my own experimental observations as to the effects of electricity when applied

percutaneously to the living man, and an experience in two cases of profound chloroform narcosis, lead me to answer quite confidently in the negative. The vagus is the chief afferent nerve for the respiratory centre, as well as the inhibitory nerve of the heart, and while it contains both accelerating and inhibitory fibres for this centre, the former largely predominate. Division of the nerve in an animal decreases the frequency of the respiration, but at the same time deepens it, while stimulation of the central end quickens it; and even were it possible to influence the pneumogastric in any marked degree by percutaneous applications, the effect on the respiratory function at least would necessarily be stimulating rather than depressing. But it must be remembered that therapeutic applications of electricity, especially the faradic current, by any allowable strength of current, has but little appreciable effect on the function of the pneumogastric.

In the case referred to in which such a profound influence was exerted over cardiac action, the application was made directly to the muscular tissue through needles, the patient being anæsthetized, and with an enormous current strength.

Percutaneously, it is possible to use only a fraction of such a strength of current, altogether too slight appreciably to affect the pneumogastric, but quite enough to excite vigorously the functional activity of the phrenic. The benefit that often comes from the use of electricity in exophthalmic goitre has been adduced as evidence that therapeutic applications do appreciably affect the inhibitory action of the pneumogastric.

According to my experience, it is the galvanic rather than the faradic current that gives the best results in this disease, while in cardiac and respiratory failure it is the latter that is both most effective and safest. But whichever current is used, it is doubtful, in the light of more recent data relating to the function of the thyroid, whether the good effects of electricity in Basedow's disease depend so much on any direct action on the pneumogastric, as on the thyroid body itself, its stimulation acting as an antidote to the hyperthyroidation believed to be the toxic cause of the symptom complex of this disease. In its report on cardiac failure in chloroform poisoning, the Hyderabad commission said that it was of "primary importance to keep track of the respiration in administering chloroform; if this is kept up the heart will give no trouble."

Apropos of this statement, a very interesting and instructive case is related by Dr. D. H. Galloway, of Chicago.[1] He described it as a case of "respiratory paralysis." Under the influence of chloroform, the face of his patient became cyanotic, respiration entirely ceased, "but the pulse was fairly good and about 140." Artificial respiration dissipated the cyanosis in a few minutes, and the pulse became stronger, but on stopping the forced respiration, all the former symptoms again returned. Forced respiration was immediately resumed and continued for some thirty minutes, with an occasional momentary cessation, but always with the same result of respiratory and heart failure. Finally, however, the respiration became permanently stronger and the patient recovered. "In every case of this kind that has come under my observation," says the author, "the chloroform has paralyzed the respiration and not the heart." Carefully conducted experiments by means of cardiographic tracings have shown that induced currents have absolutely no influence on the frequency or force of the cardiac contractions. This would seem to be a sufficient demonstration that no possible harm can come from its use in heart failure, but it does not demonstrate that this current is valueless in threatening death from this cause, as has been claimed. The promptness and ease with which the induced current, by simple percutaneous applications to the phrenic nerve, quickens and strengthens respiration, while no appreciable influence is exerted over the function of the pneumogastric, render it a most valuable agent in chloroform narcosis, as well as for the poison of opium, aconite, and other toxic agents, supposed more directly to affect the respiration.

**Summary.**—1. Direct electrization of the pneumogastric and phrenic nerves calls into activity the physiological function of these nerves. In the case of the former the action of the heart is depressed; in the case of the latter respiration is accelerated and strengthened.

2. Percutaneous applications in therapeutic doses, especially with the faradic current, altogether fail to affect the pneumogastric appreciably, while the same method readily affects the respiration through the phrenic nerve.

3. In respiratory failure, therefore, whether due to the poison of opium, aconite, or in apparent death from drowning, electrization is a powerful antidote.

4. In heart failure from chloroform narcosis also the faradic current is a legitimate method of resuscitation, by keeping up the respiration without depressing the heart.

## THE ETIOLOGY OF SCARLET FEVER.

By HARRY O. HALL,

LIBRARY SURGEON-GENERAL'S OFFICE, UNITED STATES ARMY.

In a paper upon the above subject published in the Medical Record of September 2d, the author, Dr. W. J. Class, refers to a report by Behla, which appeared in the *Centralblatt für Bakteriologie*, in which the writer speaks of a scarlet rash developing "in some pigs belonging to a peasant in whose family there were several typical cases of scarlatina. In order to see whether there was any connection between the scarlet fever in the peasant's family and the rash in the pigs, Behla took some blood from one of the children having scarlet fever and inoculated a healthy pig with it; after a few days a scarlet rash appeared around the edges of the inoculation wound, followed by desquamation."

Upon reading this quotation from Behla's paper, the question arose in my mind whether the scarlet rash which developed in the pigs was communicated to them from the infected children, or was not the disease more likely to have been communicated alike to the children and to the pigs through the medium of milk fed to them from diseased cows? It is a well-known fact that at various agricultural experiment stations milk from tuberculous cattle fed to hogs has produced tuberculosis in the hogs as revealed by post-mortem examination.

The etiology of scarlet fever is a subject which has long engaged the thought of the best minds in the medical profession, and I feel sure that anything which may throw light upon the vexed question or lead to a new line of investigation will be welcomed by medical men, even though it may come from a layman.

In the course of about twenty-five years' service in the library of the Surgeon-General's office, in connection with the compilation of the "Index Catalogue," and as custodian of the largest collection of medical journals in the world, many things have come to my observation which have started a train of thought that if followed up might have proved of value to medical science. One of the subjects which particularly attracted my attention was that of "milk as a cause of disease," and I was led to make a somewhat extensive research into the literature of the subject, which re-

sulted in revealing some very interesting if not startling facts. I learned, for example:

I. That, while scarlet fever occurs in epidemic form in all countries where cow's milk forms a staple article of food, especially among children, it does not occur in countries where cow's milk is not used as a food or where children are raised on mother's milk only.

II. That in Japan and China, where cow's milk is not used as a food, scarlet fever is unknown or very rare. (In a list of three hundred and ten different countries, cities, and towns in which epidemics of scarlet fever have occurred, Japan, China, and Corea do not appear.)

III. That in India, where cow's milk is used as a food, but where, as in Japan, children are nursed until three, four, and even six years of age, scarlet fever is rare, if not unknown.

IV. That in countries where goat's milk and ass's milk are used as a food scarlet fever is unknown.

V. That epidemics of scarlet fever in London and elsewhere have been traced directly to the use of milk from certain cows affected with the teat-and-udder disease, and that milk had not been infected by coming in contact with the disease in man.

VI. That certain diseases in the lower animals are coexistent with or precede or follow similar epidemics in the human race.

The research which brought out the above interesting facts was made several years ago after reading an account of an extensive epidemic of scarlet fever in London which was said to have been traced to milk from a certain dairy farm. Shortly after reading the account above mentioned, I came across a paper written by Dr. A. S. Ashmead, of New York, published in the *Journal of the American Medical Association*, on "The Beneficial Consequences of the Absence of Cow's Milk in Japan." This led me to wonder if in Japan scarlet fever was as prevalent as in countries where cow's milk is used as a food, and the result of my investigation showed the almost entire absence of scarlet fever from that country. So far as I have been able to ascertain, no one has heretofore connected the exemption from scarlet fever with the non-use of milk as a food. This is the point which I desire to emphasize and bring to the attention of the medical profession, especially those who are investigating the etiology of scarlet fever. To bring into apposition the several facts mentioned above I quote the following:

In December, 1885, an extensive epidemic of scarlet fever broke out in London. Upon investigation it was found that in every case the milk used by the patient came from a certain dairy farm. On further investigation it was found that certain cows in a certain shed from which the milk was supplied to the infected parties were suffering from a peculiar vesicular disease of the teats and udders. Upon the discontinuance of the sale of milk from this shed no new cases developed among the consumers; but, strange to say, upon its becoming known among the poor farmers in the neighborhood of the dairy that the milk was being thrown away, numbers of them surreptitiously obtained the milk from the cow-men, and within a short time an epidemic of scarlet fever broke out in the neighborhood, and many cases occurred. Subsequently another epidemic broke out in London among the consumers of milk from cows in a different shed of the same dairy. On investigation it was found that some new milch cows which had been kept in the quarantine shed the requisite time had on a certain date been admitted to this second shed of fifty cows. From the date of their admission the second epidemic occurred. Again the cows were submitted to examination, and certain ones were found to have discharging vesicles upon the teats and udders. Persons using milk from cows in still another shed were exempt until a certain date, when an outbreak of fever occurring among the consumers, it was found on examination that two cows in that shed were affected with the teat-and-udder disease in its early stage. Pus was taken from these vesicles and injected under the skin of healthy calves, and within a few days similar vesicles appeared upon the udders and teats of the calves, accompanied with high fever, sore throat, diarrhœa, running at the nose, and, in fact, all the symptoms of true scarlet fever.

Dr. Cameron, one of the physicians who investigated this strange epidemic, expressed his belief that the disease found to exist in the cows "was a specific disease capable of being communicated to healthy cows by direct inoculation of the teats and udders with virus conveyed by the milker from a diseased animal."

**Absence of Cow's Milk from Japan.**—In regard to the absence of cow's milk from Japan and its beneficial consequences Dr. A. S. Ashmead says:

"One of the most striking features of that most curious of countries, Japan, is the singular scarcity of domestic animals. Horses and cows are only seen in cities and on the roads as pack animals. The cow, in Japan, is not wanted for her milk. Being an animal product, milk falls under the general condemnation which excludes everything that has pertained to a living body from the alimentation of man. . . . Thus it happens that as Japan may not use cow's milk, the Japanese mothers are compelled by stress of circumstances to suckle their babes themselves. Artificial lactation is altogether unknown. The children are suckled until their sixth year. The great reward which Japan reaps from this meritorious care of motherhood is the absence of rachitism. All observers have referred to the fact, and to the absence of rachitic pelves. I think I am not wrong in affirming that the chief and central source of these great sanitary blessings is the absence of cow's milk."

**Absence of Scarlet Fever from Japan.**—Dr. Stuart Eldridge, one of the surgeons of the General Hospital of Yokohama, and secretary of the board of health of that city, in a paper published in the Medical Reports Imperial Customs of China, in 1878, says in regard to scarlet fever: "If this disease ever existed in Japan it has as yet made no appearance among foreign residents in anything approaching an epidemic form. Two cases are reported under the heading of scarlet fever as having been admitted to hospital in the years 1868 and 1870. No death from this cause is noted in the mortuary reports. The experience of the local practitioners includes but two other cases which were suspected to be scarlet fever, both occurring in the practice of the same physician, neither fatal, and both considered by the reporter as not beyond a doubt as to their character. I cannot learn that scarlatina has been met with among the natives by any prominent practitioner of medicine, either native or foreign. It is apparently but seldom met with in China. The cases above mentioned may have been scarlet fever, but it is by no means impossible that they may have been cases of any one of several other diseases known to occur here. The first case was that of an American sailor, recently arrived. Granting that this was one of scarlet fever, it is not unlikely, in view of the portability and persistency of scarlatinal contagion, that the infection was brought from home in the man's shore clothing, and that he himself fell the first and only victim. Of the second case mentioned in the hospital books, that of one of the few natives admitted for disease, the stay in hospital was so short as to prove that the disease, whatever it was, was mild, while it is very improbable that of the few cases of natives admitted to the hospital one should be that of the only known occurrence of a generally epidemic disease."

To show that Dr. Eldridge had no suspicion that the absence of cow's milk from Japan has any connection with the immunity of the Japanese from scarlatina I quote further from the same report:

"But that we have so far escaped the ravages of scarlet fever affords no certain assurance of immunity in the future. A disease of the nature of that in question, dependent upon a persistent, portable, and intense contagion, is almost certain to reach us sooner or later, while the rapid increase in the number of children in proportion to the adults of the foreign community is yearly rendering the circumstances more favorable for its propagation when once imported.

"If the theory of Dr. Carpenter is correct, and decomposing blood furnishes the origin or nidus of scarlatinal infection, the comparative rarity of collection of this form of garbage in China and Japan may be connected with the non-occurrence of this fever; or it may be possible that the existing influences of soil or climate are unfavorable to the development or propagation of the specific poison. But the relations of such conditions to the disease in question, if they exist, are so little understood that it will be the part of wisdom to treat any suspicious case with exceptional precautions against the propagation of the malady."

**Scarlet Fever Rare in India.**[1]—Surgeon-Major Murray, of Bengal, in an article in *The Lancet* for October 27, 1888, in discussing a case of sporadic scarlet fever originating *de novo* in India, says:

"Cases of scarlet fever are so extremely rare in India that the publication of the following case may be of interest. Chevers, in his last work (a commentary on the diseases of India), writes: 'I never saw any form of scarlatina in lower Bengal, or any disease which could be mistaken for it; neither has any medical man with whom I have discussed the subject met with a genuine and unmistakable case in that great province.'

"Writing in 1864, Dr. Peet, who had great experience in the Bombay Presidency, said: 'Scarlet fever is altogether unknown in Western India.' Deputy Surgeon-General G. Mackay, an officer of large experience, who spent all his term of service in the Madras Presidency, and was for several years civil surgeon of Ootacamund, never saw a case of the disease in India. A few cases have been reported as having occurred at military stations in the families of soldiers recently arrived from England—imported cases."

To what extent milk is used in India as a food I am not able to say, but it is not customary to feed it to infants or young children. In an article running through two volumes of the *Indian Medical Gazette*, on the infantile diseases of India, Dr. T. R. Hogg, the writer, says: "As families subsist on four rupees a month, the mother feeds on dal, chupatties, rice, rarely varied by the luxuries of sheep's head or goat's flesh. The child is kept at the breast without any other nourishment as long as possible; the period of lactation is prolonged three years or more, and so long as an infant thrives and gains weight on suitable breast milk only he is preserved from sickness or the dangers of dentition, and is less prone to contract worms or infectious fevers."

Even if it should be found that in countries where cow's milk is commonly used as food scarlet fever is rare or unknown, it would be interesting to know more about the cattle of the country, the character of their food, and the nature of their diseases, etc., before we arrive at any conclusions.

One fact is beyond any dispute; that is, that many diseases, and particularly tuberculosis and scarlet fever, have been traced directly to milk consumed. The questions to be decided is, Can these diseases, or do they, originate in the cows?

Writing on the subject of "the diseases of the cow by which infection is conveyed to the consumer of her milk," Dr. H. E. Armstrong says: "It has been clearly demonstrated that milk may of itself be diseased as the product of a diseased animal. Foot-and-mouth disease, as is well known, is transmissible from quadruped to man. So is tuberculosis. During recent years several outbreaks of human scarlet fever and diphtheria have been undoubtedly due to milk supply.

"In some dairy farms cows have been found to be ill, their most noteworthy symptoms being febrile disturbances, vesicular eruptions on the udder, scabbed teats, and a loss of hair in patches. The investigators report that these symptoms indicate a disease or diseases in the cow which are communicable, as scarlet fever or diphtheria, respectively, to the consumers of the milk."

In an epidemic of scarlatina occurring at Wimbledon, it was found that out of five hundred and forty-five cases of the disease four hundred and ninety-three occurred among a population of about fifteen hundred persons using milk from a certain suspected dairy, while but fifty-two cases out of a population of fifteen thousand persons using milk from other dairies occurred.

In another outbreak of scarlet fever three children in one family who were fed on a particular cow's milk caught the disease, and one died. The only other child in the family, supplied with milk from a different dairy, escaped entirely.

Very few persons whose attention has not been drawn specially to it have any conception of the enormous quantity of milk consumed in our large cities. When we look at the figures and compare them with the high death rate of children and infants, the importance of throwing every safeguard about this almost necessary article of food will be apparent. Averaging the daily consumption of milk per capita at two-thirds of a pint, the amount consumed in New York is one hundred and eighty million quarts at a cost of $13,500,000; in Philadelphia, seventy-five million quarts. In a total city population of a few principal cities of five million there are annually consumed over four hundred million quarts of milk, costing the consumers $32,000,000.

**Connection between the Diseases of Animals and Man.**—While it is true that the idea that cow's milk may become the vehicle of communicating disease to man is of recent origin, it has long been known that many of the diseases of animals bear a great similarity to certain diseases in man, and that many of the diseases with which we are now afflicted were originally peculiar to the lower animals. It has also been observed that epidemics of certain diseases in the lower animals are coexistent with or precede or follow similar epidemics of disease in the human species.

A reference to George Fleming's work on animal plagues from B.C. 1490 to A.D. 1800 reveals many very interesting facts in this connection.

The learned historiographer of Barbadoes, the Rev. Mr. Hughes, describes the disease scarlatina, and its

[1] Since the above was written the following paragraph in the MEDICAL RECORD of September 16, 1899, has come under my observation: "The *Journal of Tropical Medicine* says that the *Indian Medical Gazette* has since 1870, collected a considerable amount of information regarding the prevalence of scarlet fever in India. Up to that time it was believed that the disease was unknown in that country. Colonel Kenneth Macleod, writing to the *Journal of Tropical Medicine* on the matter, comes to these conclusions: (1) That scarlet fever has been frequently imported by troop ships and that small epidemics have thus arisen among Indian natives in children. (2) That these epidemics have always been of a limited kind and have speedily died out. (3) That they appear to be more substantial and protracted in hill stations than on the plains. (4) That cases and groups of cases have been observed, the origin of which could not be ascertained. (5) That the disease does not appear to prevail epidemically among indigenous races and populations."

conveyance to human beings "both by contact with the diseased animals and by eating their flesh and drinking their milk."

In 1778 scarlet fever and epidemic angina in mankind were very prevalent in many countries, but particularly in England and Holland, and an epizoötic among cattle, horses, asses, goats, pigs, etc., appeared.

In 1777 scarlet fever was epidemic in many countries, and in England and France was complicated with malignant sore throat and diphtheria. In March of that year angina gangrenosa developed among horses.

In 1514 Fruscator described a pestilential exanthematic or eruptive fever among animals somewhat like the measles or purpuric fever in man, but more particularly resembling the scarlet fever of Sydenham, or the malignant miliary fever as described by Hamilton and Alloni, but more exactly by Waltherius. An eruption appeared on the face, ears, neck, and forelegs, attended with sore throat. It was a kind of quinsy, followed by eruption. In 1735 angina ulcusculosa, or scarlet fever, prevailed for the first time in America. In 1734 scarlet fever was epidemic in England and Scotland, and nephritic colic among horses. There was also an epizoötic among horses in England and Scotland, which Hensinger thinks may have been scarlatina. In 1760, in the county of York, England, during February and March, scarlatina, sometimes complicated with malignant sore throat (diphtheria) was epidemic in the human species. At the same time an epizoötic manifested itself among horses, which affected every animal in the locality with symptoms very similar to those observed in mankind. One hundred died in a week.

In 1768–69 an epizoötic anthrax in animals was prevalent in Switzerland, coincidently with gangrenous sore throat; malignant pustule and epidemic diseases such as scarlet fever and angina were common in the human species.

In Copeland's "Encyclopedia of Medicine" we read: "I have lately had reasons, indeed evidence, for the following inferences: (1) That scarlatina was originally a disease of the horse, and that it formerly occurred, and has recently occurred epidemically, or as an epizoötic among horses. (2) That it was communicated in comparatively modern times from horses to man; (3) that it may be, and has been, communicated also to dogs."

Mr. Percival, veterinary surgeon to the First Regiment of Life Guards, in his work says: "Like smallpox, scarlet fever was first generated in the lower animals . . . and was then communicated to man."

In a paper entitled "Consumption Caused by Cow's Milk," published in the *Medical and Surgical Reporter*, April 29, 1893, Dr. McQueston, the writer, says: "Consumption is the result of drinking cow's milk, and where milk is not used the disease is said not to occur. I mean exactly what I say," he continues, "no more, no less. The primary cause of consumption is the drinking of cow's milk. I do not mean that every single case of phthisis is attributable directly to the patient's having imbibed infected cow's milk—though even so strong a statement as that is very nearly true—but I do mean to say that if the American people stopped using cow's milk, and butter and cheese made from cow's milk, tuberculous consumption would soon disappear. Let met put it in another way: In countries where cow's milk is not used tuberculous consumption is not known. In China there is no milk consumed, and consumption is almost an unknown quantity. Take the steppes of Asiatic Russia: only goat's milk and mare's milk is used there. Consequently there is no consumption. . . . The same condition is, or was until recently, true of the South Sea Islanders—no cows, no tuberculous diseases. Take the North American Indians before the white man brought his whiskey and his cows among them. They had no word in the Indian language that corresponded to consumption. A few cases may be produced by the person inhaling the dried sputa, and some may be inherited, but the great cause, and the first cause, is the use of cow's milk as a food."

The conclusions arrived at by Dr. McQueston in regard to consumption in its relation to cow's milk, from investigations made by him, are identical with those of the writer of this paper in regard to scarlet fever in its relation to cow's milk, arrived at after an entirely independent investigation.

If the facts cited above, and the suggestions thrown out shall result in a new line of investigation by medical men as to the etiology of scarlet fever, I shall feel fully repaid for the trouble I have taken in preparing this paper.

## IODIDE OF POTASSIUM IN THE TREATMENT OF ACNE.

By FRED. J. LEVISEUR, M.D.,
NEW YORK.

It seems to be paradoxical to claim that iodide of potassium administered internally is useful in the treatment of acne vulgaris. The well-known fact that this drug is liable to produce papulo-pustular cutaneous manifestations closely resembling the lesions of acne apparently favors its avoidance rather than its use. Practical experience while treating a number of acne patients with iodide of potassium has convinced me that the action of the drug is in many regards quite different from what one is led to expect, and that it can be utilized very well in the treatment of this stubborn disease.

As is well known, the escape of free iodine through the skin has been observed by R. W. Taylor. It has been found in the blood, in pus, in pleuritic exudations, in the mucus of the bronchi, in the fluid of hydrocele and synovia, in the milk, the nasal mucus, in the tears, the sweat, the crystalline lens and vitreous humors, and, according to Howald, in the hair.[1] In the pus of acne pustules or tumors of iodic origin it was found by Guttmann and Adamkiewicz, while Ducrey's, Pellizary's, and Hyde's identical experiments were followed by negative results.

Spenzer,[2] of Cleveland, advanced the theory that hydriodic acid is formed primarily, and other writers state that more complicated chemical combinations occur in the sebaceous follicles on account of the presence of fatty acids. One author is, I think, carried away by his imagination when he says that these chemical reactions are sometimes so intense as to produce nascent oxygen (ozone), which, when set free, acts as a strong irritant. Even if the presence of iodine in some of the normal secretions and in the pus has been demonstrated, there is no foundation for the belief that the lesions of iodic acne are produced as if the iodine was injected into the follicle from the outside. Modern investigators like Thin, Colcott, Fox, Gibbes, and Unna have shown that a primary inflammation of the sebaceous glands does not exist, but that the papules and pustules must be considered as a superficial dermatitis together with the formation of minute abscesses in the cutis, all this being the result of the disorganization of small blood-vessels at special points through the iodine circulating in the blood.[3] Of interest in this connection is the well-known inflammatory reaction produced by dusting calomel into the eye of a patient who is taking some

[3] Vorhandlung d. deutsch. derm. Gesch., vi. Congress, 1899.

iodide preparation internally.[1] Fricke[2] was the first to call attention to this phenomenon, which occurred in the cases of two patients who had been taking hydriodic potash, one for twenty-eight and the other for thirty-six days. He then made experiments on healthy persons, producing the same results. He was unable to prove the presence of iodine in the lacrymal secretions. Thirty years later Edmund Rose, Hennequin,[3] and Lagarde[4] took up the same subject. Hennequin's patient was given iodide of potassium in about gr. ix. daily doses for ten days; then calomel was insufflated into the eye, producing an effect as if some caustic chemical had been applied to the conjunctiva. Bellini, who was the first to make experiments with animals, found that if about nine grains of iodide of potassium was administered twice daily, the excretion of the iodine as shown by urinary analysis was constant. He also drew attention to the fact that calomel is ten times more soluble in a three- to four-per-cent. solution of salt than in ordinary water. He believes in the formation of a chemical combination of iodine and mercury. Glancing through a number of standard works on the eye,[5] selecting the chapter on phlyctenular ophthalmia, we find that some writers do not use mercurials in the eyes, and hence have no occasion to mention the phenomenon; others speak of calomel and Pagenstecher's ointment as useful, but give no caution as regards iodide of potassium. Some warn against calomel, but in the same paragraph recommend other mercurials, while others proscribe all mercurials. Many writers mention only iodide of potassium, while others include iodide of iron and in fact all iodine salts. Fuchs quotes Schlaefke as authority that the compound formed is mercuric iodide, while Mittendorf says that the irritating substance formed by the iodide is an oxide and not an iodide of mercury. It is quite important to note that many writers agree on two points, viz., that small doses of iodide of potassium may produce the phenomenon, and that it may occur comparatively soon after the beginning of the medication. Acute iodism also may appear soon after the administration of one or two small doses. I do not refer to the iodism occurring in patients with nephritis or heart lesions, for according to O. Reichel and J. Neumann[6] resorptive activity and consequently the vitality of the skin and mucous membranes are materially interfered with in these patients. Kessler[7] tells of a case caused by an iodide of potassium and glycerin vaginal tampon. A few moments after the introduction there were burning sensations with lancinating pains in the abdomen, iodine taste, and pains in the lateral aspect of the face and neck. He also quotes Fournier[8] as having seen three cases of œdema glottidis after small medicinal doses. Hewkley[9] reports a case of acute iodism, in which iodide of iron had been given in moderate doses, the characteristic symptoms soon following the exhibition of the drug. Similar cases are also mentioned by Briquet,[10] Russell,[11] and Finger.[12] I have observed that if patients with normal renal functions, having acne vulgaris, take gr. v. of iodide of potassium three times a day in a glass of milk, symptoms of what might be called acute iodism appear as early as after two or three doses, and not later than on the third day. The symptoms consist in the appearance of a metallic taste, running from the nose, and a feeling of pressure in the frontal region. Aside from the subjective symptoms, which being slight are noticed only by intelligent patients, nodules appear in the apparently healthy skin of the face, of the size of a pea. They are deeply embedded in the skin, somewhat but very slightly redder than the surrounding parts, and moderately painful on pressure. They resemble urticaria wheals,[1] or, better yet, a diminutive form of a lesion of erythema nodosum. At the same time acne lesions if present, especially the old indurated ones, show a sudden increased inflammatory reaction, resembling very much the reaction occurring in and around lupus nodules after the injection of tuberculin.

I shall not try to explain the appearance of this peculiar early iodism after small doses, but would like to point out that according to v. Cyon[2] the iodide salts circulating in the blood, after being transformed rapidly into an organic combination, are changed into iodothyrin by the action of the thyroid gland. This gland may, therefore, play an important part in this connection. If larger or very large doses ( ℥ i. to iss.) for psoriasis (Haslund[3]) are given, it is quite possible that through the action of the drug on the kidneys the iodine is eliminated more as an alkaline iodide, and not so much in organic combination.

In all the cases, numbering about fifty, treated by me with iodide of potassium, this drug was administered in milk. The therapeutic action of the iodide is in no way interfered with by giving it in this vehicle, but it is rendered more acceptable to the stomach; a considerable quantity of the iodine (0.17 to 100) becoming neutralized by the alkali and albuminates contained in the milk. The average dose was iodide of potassium gr. v. three times a day. In almost all cases the urine was tested for the presence of iodine. This test is, I have found, quite simple. Some urine poured into a test tube is mixed with one-third of its volume of ordinary corn starch. Then a drop of commercial nitric acid is allowed to run down inside the tube. The latter should not be held in the hand, but should be put into a glass standing on the table, so as to keep the tube perfectly quiet. If iodide is present in the urine the drop of acid, running down into the mixture, will form a streak bordered by a blue or violet color, which gradually disappears. The presence of one part of iodide of potassium in six thousand can easily be demonstrated. As a rule the iodide appeared in the urine after two or three doses on the second day, and had entirely disappeared about forty-eight hours after the medication had been discontinued.

The following case illustrates the manner of treatment.

Miss F. W——, eighteen years old, had been affected with acne of the face for a year and a half. The affection started with the formation of pustules on and around the nose, the region of the forehead and the chin becoming gradually involved. In spite of judicious and thorough treatment, both by external and internal remedies under the direction of the family physician, and later of several specialists, the patient's condition became worse. A number of tumors appeared, varying in size from a ten-cent piece to a quarter, protruding well above the surface of the skin, of a bluish-red color strongly contrasting with the somewhat sallow complexion of the patient. Here and there a number of ordinary acne pustules were inter-

spersed, and several unsightly scars were noticed marking the site of lesions which had been opened by the knife and emptied, according to the patient, of a considerable amount of pus. The patient was given gr. v. of iodide of potassium three times a day in a glass of milk after meals. The following day—after three doses—she complained of a slight headache, running from the nose, and a pronounced metallic taste. The urinary test for iodine was positive. On the third day the condition presented a decided change. All the larger tumors showed increased redness, swelling, and pain on pressure. There were also present a number of new lesions (four) consisting of small nodules deeply embedded in the skin, of the size of a small pea, almost normal as regards color, but decidedly painful on pressure; they were not capped by a pustule nor was there a central opening indicating their connection with a sebaceous gland. The iodide of potassium was now stopped, and the face treated locally with a mild sulphur salve and ichthyol soap ten per cent. At the end of the second week the patient's face had greatly improved. All the larger tumors were very much diminished in size; the smaller, due directly to the iodide, had entirely disappeared. There were no pustules present. The iodide of potassium was now given in the same doses and manner as before. Symptoms of early iodism again appeared on the second day, the urine containing traces of iodine. The local reaction concerning the lesions in the face was not so intense this time, still it was plainly visible. After three days a number of new pustules appeared. The iodide medication was now stopped, and under the influence of ordinary local treatment, which hitherto had been absolutely inefficient, the patient got perfectly well, and could be pronounced cured at the beginning of the fifth week. This case represents that type of acne for which iodide treatment is particularly well adapted. But the latter has also shown its value in other chronic cases of acne in which there exists less inflammation, but in which many comedones are present. In these cases it is necessary to stop the treatment promptly as soon as signs of a reaction have made their appearance. Patients, therefore, need careful watching, and should be required to report to the physician every three or four days. The urinary test for iodine, as described above, should always be made.

## ENTRANCE OF AIR INTO THE CIRCULATION.

By J. D. MacPHERSON, M.D.,

Akron, N. Y.

How often air enters the circulation, or in what per cent. its presence there would cause a fatal issue, might be a matter for some experimenter to ascertain. That fatalities do occur from this cause in obstetrical and surgical cases is no doubt true. Many of the so-called cases of embolism in obstetrical practice are in reality due to the churning of air in the heart cavities instead of the lodgment of a clot as often supposed. Nicking of the external jugular, in which the blood pursues a downward course, has always been carefully avoided by surgeons to exclude the possible entrance of air which might be carried directly to the heart in its downward rush.

Every one is familiar with the action of a pump working smoothly and well. If a little air is admitted along the line of suction, what is the result? Instantly the valve forgets to work. The stream pours out in foam. Precisely this occurs upon the entrance of air into the circulation. The heart cavities become filled with foam, and instantly there is a case of the much-mooted but nevertheless genuine heart failure. Any one who has been unfortunate enough to witness such a case will never forget the awful agony depicted by a patient in such terrible condition as above described. The intent of this article is particularly to call the attention of post-mortem examiners to the necessity of examining for air in the cavities of the heart and coronary arteries in cases of sudden death, especially those in which an abortion may presumably have been attempted or performed. When the chest cavity is opened and the heart exposed the coronary arteries should be examined carefully for the presence of air. If present, a crackling sensation will be felt by the finger. It may also be seen to be present by the blood column being divided into sections. When the finger is drawn along the transparent walls of the artery, the blood may be seen to move in divided portions as above related. A further demonstration will be had when the heart cavities are opened, the foamy character of their contents being manifest.

A common method among the laity for the induction of abortion is to introduce the nozzle of a syringe, with perhaps a catheter attached, into the uterus, and to inject water, or what must be the inevitable result with the novice, air. These people are not discriminating as to technicalities; it is results they are after. Therefore should they choose a bulb syringe and not divest it of air by submersion previous to its introduction, as the nozzle completely blocks the os, the air must go somewhere, and that blast of air from the rear door will cause the recipient a cold which will send her travelling through the balmy altitudes of space in search of cure.

That these and like procedures are the causes of numberless cases of sudden demise I am convinced. There being no ostensible signs, often the case is passed upon as angina pectoris or some of the manifold heart lesions. Imagine the sigh of relief the operator must draw when he reads the autograph of the careful family physician attached to the legal certificate which forever hides from public inspection the real cause.

Think of the lifelong wonder it must be to the ignorant quack, husband, or other accessory (if there is any) why heart failure should set in at such an inopportune moment.

Typhoid and other cases of ulcerating diseases of the intestine often drop out suddenly from some mysterious cause. May not an explanation be found in the introduction of gases into the circulation through the medium of sappy ulcerations and open vessels which oftentimes exist in hemorrhagic cases? The pressure of gas in cases of great tympanites is sufficient to force air into the circulation and thus furnish us a clew to our patient's sudden collapse.

Physicians should use care, in giving hypodermic injections, to divest their syringes of air before use. This rule might safely be applied even to rectal enemata. Another more recent and equally dangerous practice, by which air might enter the circulatory system, is that arising from carelessness in throwing peroxide of hydrogen into a cavity like the bladder or uterus, or even a large abscess cavity, the danger accruing from the rapid development of gas by the action of the peroxide on pus or blood. There being only a small outflow, or none at all, pressure might become great enough to force air into the circulation.

**Posterior Urethritis.**—Irrigations with the recurrent catheter, of permanganate of potassium, followed by injections of protargol, will cure in a relatively short time a case of subacute posterior urethritis without complications.—A. Ravogli.

# Progress of Medical Science.

**Spontaneous Healing of Tuberculous Ulceration of the Larynx.**—Eiserbarth (*Deutsches Archiv fur klinische Medicin*, B. 65, H. 1 and 2, p. 205) has reported the case of a laborer, forty-seven years old, who first came under observation June 8, 1897, and again on August 8, 1898, principally on account of pulmonary tuberculosis. In the interval difficulty in swallowing developed, and the voice became hoarse. Laryngoscopic examination yielded negative results by reason of mechanical difficulties. On dismissal, toward the close of October, 1898, the symptoms were referable principally to the larynx. In the middle of January, 1899, the patient came under observation for the third time with severe pain in the larynx. Laryngoscopic examination was difficult, but finally a large cicatrix involving the right vocal band and ventricular band was brought into view. Treatment was directed against the principal disorder, the tuberculosis of the lungs and the intestine. Death took place on February 6, 1899, and on post-mortem examination the larynx presented evidences of previous extensive tuberculosis, which had undergone perfect and complete cicatrization.

**Paroxysmal Swelling of the Parotid Glands.**—Freudenthal (*Berliner klinische Wochenschrift*, October 2, 1899, p. 80) has reported the case of a woman, thirty-two years old, who as a child had suffered from glandular enlargement and between the age of thirteen and twenty-two years from anæmia. For ten or twelve years the patient was from time to time suddenly seized with itching in front of the ear, and more frequently upon the left side, this area in a short while becoming intensely red. At first swelling was absent, but within six years the slightest irritation of the itching area, as from scratching, was followed by the appearance of a swelling half as large as a goose egg. Without interference this condition subsided spontaneously in from ten to thirty minutes. At no time was the secretion of saliva excessive, and the saliva never contained pus. During the first pregnancy three years previously, as well as during the second, in the fourth month of which the patient came under observation, the condition, which ordinarily recurred daily, remained entirely in abeyance. The patient was anæmic and lymphatic, and somewhat adipose. The heart was slightly enlarged, and the stomach dilated and atonic. Some of the teeth were distinctly carious. Febrile symptoms were absent. No relation existed between the appearance of the swelling and menstruation. The condition was considered most probably hysterical. A further unique feature of the case is the circumstance that the husband of the patient on two occasions with an interval of six months was likewise seized with sudden swelling in the parotid region on both sides, preceded by itching and redness of the skin. The swelling persisted for about a day and a half and then disappeared spontaneously. This condition also was considered hysterical.

**A Case of Scarlet Fever Associated with Tetany in a Child.**—Kühn (*Berliner klinische Wochenschrift*, September 25, 1899, p. 855) reports the case of a boy, four and a half years old, in whom stiffness and impaired mobility of the lower extremities had been observed for five days. These symptoms gradually increased and slight fever appeared. The teeth were tightly clenched, the neck was rigid, and slight opisthotonos and rigidity of the extensors of the lower extremities were present. The arms were held close to the body by tonic contraction of the shoulder-muscles and of the flexors, while the hands were free and consciousness was preserved. The eyeballs also were freely movable. Upon the face and the anterior surface of the extremities were isolated red spots, from a millet-seed to a lentil in size. On the chest the skin presented a diffuse, dark, punctate, pale-red color, upon the abdomen with a yellowish-brown tint. The back, from the neck to the buttocks, presented a homogeneous, deeply scarlet-red, somewhat swollen surface, covered with numerous miliary vesicles. Miliaria were present also upon the neck and the abdomen. The urine was free from albumin and sugar, and the glands behind the jaw were not enlarged. The trismus and the rigidity of the neck remained unchanged during rest, while the stiffness of the remainder of the body yielded somewhat. Attempts at passive movement and pressure in the bicipital and crural sulci, however, increased the rigidity and transformed the tonic into clonic spasm. The mechanical irritability of individual nerves and muscles was greatly increased. No injury or recent cicatrix could be detected, and the possibility of intoxication with ergot or strychnine could be excluded. Desquamation set in at the end of a week, while the spasmodic phenomena persisted for six weeks.

**Cardiac Arrhythmia.**—As the result of an interesting clinical and anatomical study Ebstein (*Deutsches Archiv für klinische Medicin*, Nos. 1 and 2, vol. 65, 1899) concludes that all disturbances in the rhythmic activity of the heart, which so often come under clinical observation, may be explained in accordance with the results of experiments on animals. Arrhythmic cardiac activity in both human beings and animals is the expression of increased demands upon the activity of the heart when the cardiac cavities are overfilled with the blood, and when a disproportion exists between the circulatory resistances and the functional capability of the heart. These facts are of clinical significance, and often constitute important guides in prognosis and treatment. On the other hand, a trustworthy conclusion with regard to the influence disturbing the regularity of cardiac activity cannot be based upon the arrhythmia, of whatever character, intensity, and duration it may be. This is possible in many cases, but by no means in all, from a consideration of the etiological influences, upon careful and thorough investigation of the patient.

**Neurectomy as a Preventive of Masturbation.**—In *The Lancet* of September 23, 1899, A. C. and H. E. Clark report the case of an insane man, forty-nine years old, in whom the habit of masturbation was controlled by division of the afferent nerve of the reflex circuit, with the object of preventing erection and sensation. After careful antiseptic preparation an incision was made transversely across the dorsal surface, and about half an inch from the root of the penis. The skin here being elastic and flaccid it can be drawn into a longitudinal fold, and this is easily transfixed transversely by a sharp, narrow-bladed knife, without injury to the dorsal vein. The nerves, two in number, are not easy of identification or isolation, being intimately wrapped up in the loose superficial fascia. They must be sought for on the lateral margins of the dorsum of the penis, and they are in close relation to and generally to the outer side of the dorsal arteries. The arteries are more closely attached to the capsule of the corpus cavernosum, and they are not, therefore, liable to be injured. The nerves were raised by means of a blunt hook, and about half an inch of each was resected. The wound was closed by a continuous catgut suture, and, being made thoroughly dry by washing with ether, a layer of thin gauze was made to cover it by means of collodion. The healing

process occupied ten days, and the patient made a satisfactory recovery. The man was much depressed for some time after the operation, but he had given up his former habit, and he was much improved mentally. There was no atrophy of the testicles after the lapse of a year.

**Differential Diagnosis between Intermittent Fever and Acute Tuberculosis.**—At the meeting of the French Academy of Medicine, in September, 1899, Dr. Moncorvo, of Rio Janeiro, spoke of the value of guaiacol as an application in deciding between malarial fevers and acute or subacute forms of tuberculosis in early life, and presented the following conclusions: (1) The antithermic action of synthetic guaiacol (alpha) employed under the form of a cutaneous dressing is very active and very prompt in the fever due to tuberculosis, while it remains almost without exception negative in instances of malarial fever. (2) This diversity of action of guaiacol lends to it an incontestable value in clearing up the diagnosis between tuberculosis and acute malaria. (3) Guaiacol employed in the same manner also aids us in the diagnosis when these two affections coexist.

**A Convenient Test for the Presence of Acetone in the Urine and Other Animal Fluids.**—Oppenheimer (*Berliner klinische Wochenschrift*, September, 18, 1899) recommends the following test for the detection of the presence of acetone in the urine and other body fluids. First, a reagent of the following composition is prepared: Mercuric oxide 50, concentrated sulphuric acid 200, distilled water 1,000. The sulphuric acid is first added to the water, and then the mercuric oxide, and the whole is permitted to stand for twenty-four hours, when it is filtered. To 3 c.c. of urine the reagent is added drop by drop. In the presence of albumin a turbidity results at once, but in the absence of albumin only after addition of considerable quantities of the reagent. If the precipitate remains on shaking, a few drops more of reagent are added, when the mixture is set aside for two or three minutes until a viscid sediment forms. Next filtration is practised, and repeated if necessary, until the filtrate is clear. Then about 2 c.c. of the reagent is added, and 3 or 4 c.c. of thirty-per-cent. sulphuric acid, and heat is applied for one or two minutes, over a flame or over boiling water. If a dense white precipitate appears in the course of two or three minutes it may be concluded that acetone is present. If the amount be small, less than 1 in 50,000, the turbidity may not occur for three or four minutes. The precipitate is soluble in an excess of hydrochloric acid. The test can be performed in from five to seven minutes, and it requires no special apparatus. It must, however, be performed exactly in the manner described. The test is applicable also for quantitative analysis.

**Surgical Treatment of Gastric Ulcer.**—In the *Annals of Surgery* for October, 1899, Andrews and Eisendrath report two cases of gastric ulcer in which operation was performed, in the one with a successful and in the other with an unsuccessful result. As an outcome of this experience and of some experiments on animals, together with a consideration of the cases recorded in the literature, they reach the conclusion that the result of the practice of the best modern surgeons warrants the statement, previously made on theoretical grounds, that operative intervention only can save the lives of a certain proportion of the patients affected with bleeding ulcers of the stomach, viz., those not improved by internal medicine. Surgical intervention is to be recommended, first, in cases presenting small repeated hemorrhages; second, in cases of severe hemorrhage occurring more than once, especially if more than 500 c.c. is lost at each bleeding. A single copious hemorrhage is not necessarily an indication for operation. In cases with ulcers at or near the pylorus, pyloroplasty is an ideal operative procedure. It renders local treatment possible, and yields all of the benefits of and is safer than gastroenterostomy. Cauterization and curetting of the ulcer should give place to resection, whenever the stomach wall can be reached from without. If the stomach is adherent posteriorly or at either extremity cauterization, curettage, and ligature *en masse* are the best substitutes for excision. Ligature *en masse* has been shown experimentally to favor perforation, unless support is afforded by external sutures.

**Some Facts in Regard to Aneurism of the Aorta.**—H. A. Hare and C. A. Holder (*American Journal of the Medical Sciences*, October), in closing a paper on aneurism, have called attention to several facts which they thought to be noteworthy, as follows: First, the far greater frequency of this lesion of the aorta in males than in females; secondly, the far greater frequency in the involvement of the ascending portion of the arch than of the other portions; third, the fact that aneurisms of the transverse and of the descending portions of the arch seem to be about equally frequent; fourth, that in a large proportion of cases death did not ensue from rupture, but from pressure by the growth; fifth, that syphilis does not seem to play so large a part as an etiological factor as is supposed, although this evidence is negative rather than positive, since it is possible that many of the cases which were assigned to trauma as the cause are really dependent upon syphilis, in that this disease had primarily weakened the aortic wall so that injury readily brought about aneurism. The analysis included the histories of nine hundred and fifty-three cases taken at random from the reports of the clinicians in this country and abroad.

**Spasmodic Asthma.**—W. Blair Bell (*The Edinburgh Medical Journal*, October) considers briefly the causation of asthma as follows:

1. Direct Causes in the Lungs: (*a*) Mechanical and toxic irritation (external). This may be caused by inhalation of vapors, cold air, or dust (*i.e.*, solid irritants). The result is usually immediate, and may disappear when the cause is removed. (*b*) Mechanical and toxic irritation (internal), by elimination of retained or toxic compounds in the blood in cases of gout, rheumatism, Bright's disease, intestinal intoxication, and uterine disturbances, especially in pregnancy. (*c*) Pathological conditions of the lungs. Tubercle, bronchitis (acute and chronic), bronchopneumonia, etc., may all be accompanied by asthma.

2. Indirect Causes: These indirect causes convey their impressions to the lungs through the branches of the vagus nerve, which has a pulmonary plexus. The peripheral branches have widespread connections, and by far the most important in the causation of asthma is the gastric branch. (*a*) Gastric irritation. In a large proportion of the attacks of asthma in children here lies the cause. The reflex result takes place along the course of this gastric branch. (*b*) Nasopharyngeal and aural. These can be studied in any text-book on anatomy concerning the connections of the vagus with these regions. Polypi, adenoids, enlarged tonsils, catarrh, etc., are frequent causes of asthma. (*c*) Cardiac. It has been shown that "cardiac asthma" in a general way is not asthma at all, in the true sense of the word, but there is a true cardiac asthma which arises from the irritation of the cardiac termination of the vagus, and produces a reflex irritation of the pulmonary plexus. It is very rare, and it is the result of myocarditis and possibly pericarditis. (*d*) Central. Central irritation is caused through

the channels of the ordinary sense of touch, sight, hearing, smelling, or by mental impressions—fright, emotion, etc. Direct impulses are transmitted along the vagus to the lungs from the central nervous system.

**Beta-Eucaine as an Anæsthetic.**—William H. Poole (*Medical News*, October 21st) concludes that: (1) Eucaine is decidedly less toxic than cocaine, therefore superior to it. (2) Its aqueous solutions keep well and can be sterilized by boiling without destroying the activity of the drug. (3) It produces anæsthesia equally well and sometimes better than cocaine. (4) It is superior to cocaine in that it does not cause heart depression or other unpleasant effects. (5) It does not cause mydriasis or disturbances of accommodation, which is of advantage in some cases. (6) It is less dangerous to the cornea than cocaine, inasmuch as it does not cause desquamation of the superficial epithelium.

**Diagnostic Value of Radiography in Children.**—Escherich (*Centralblatt für die medicinischen Wissenschaften*, September 30th) says that radiography in children, on account of the extreme thinness of the tissues, is very satisfactory. The shadows which the bones produce are, however, less sharply defined than in adults, a condition which is explained by the fact that their bones contain less calcium than those of adults. In a rachitic child, an attempt was made to determine by means of the *x*-rays the effect of a phosphorus therapy. A change in the bone picture was not observed after a long-continued administration of the phosphorus, but the "bone-forming" zone of the forearm showed a somewhat less irregular course. The mediastinum did not furnish any useful pictures. On the other hand, the diaphragm gave sharply defined pictures, enabling one to follow the position and movement of the muscle. The heart gave very dark shadow pictures. By means of these, it was shown that in some children with post-diphtheritic paralysis a marked displacement of the heart exists; this is a sign which speaks for an unfavorable termination. The shadow picture of a normal heart stretches far wider than the zone of so-called relative cardiac dulness; the borders must be determined separately for the various ages. The dark cardiac shadow is in marked contrast to the light pictures which other muscles present. It is quite easily demonstrated that a heart emptied of its blood gives a light shadow. Therefore the fluid contents are the cause of the dark cardiac pictures. Further demonstrations showed that not the hæmoglobin but the fluid itself gave rise to the dark pictures. A heart filled with water gives the same dark shadow as a heart filled with blood. All other organs as well, once they contain a large quantity of water, give dark shadows; for instance, the lungs in pulmonary œdema.

**Pathology of Gout.**—Kionka (*Münchner medicinische Wochenschrift*, October 3d) draws the following conclusions: (1) Just as an excessive meat diet in human beings gives rise to gout, so in fowls that have been fed exclusively on meat do we observe an analogous clinical picture. (2) The gout of birds presents both clinically and pathologically the same symptoms as the uric-acid arthritis of human beings. (3) The uric-acid excretion in fowls that have been fed on an exclusive milk diet is markedly increased. (4) After the administration of calcium salts the uric-acid excretion in these fowls sinks fifty to sixty per cent., probably on account of the formation of carbaminic acid. (5) In human beings, carbaminic acid is also formed after continued administration of calcium; whether by this means the formation of uric acid is diminished, as in fowls, is very questionable, though numerous analyses by Strauss and Herxheimer seem to show a proportionate reduction of twelve to thirteen per cent. (6) The treatment of gout and the uric-acid diathesis with mineral spring waters is to a certain degree a calcium therapy, in that all the mineral water used for the purpose shows by chemical analysis a large percentage of calcium.

**Hysterical Skin Affections.**—Rasch reports an instance of factitious dermatitis with gangrene in a girl aged eighteen years (*Dermatol. Centralblatt*, August) which on close investigations turned out to have been caused by application of cantharides. Some lesions were followed by scar keloid. From the literature he gathers many instances of supposedly hysterical gangrene, etc., which subsequent investigation showed to be self-inflicted injuries, and he believes that in general an artificial origin cannot with certainty be excluded in these peculiar cases.

**Early Diagnosis in Pulmonary Tuberculosis.**—Dr. S. G. Bonney, of Denver, writing in the *Medical News* of September 30th, says the character of the cases sent to Colorado presents a striking commentary on the necessity of a more thorough appreciation of the principles capable of every-day application upon which to base an early diagnosis. After speaking of the significance of morning cough, daily rise of temperature, etc., he says: "The initial occurrence of hemorrhage without readily assignable cause should furnish, even in the absence of all clinical manifestations, all physical signs, a strong, suggestive indication of the existence of an already active though limited focus of tuberculosis infection." He condemns: (1) Delay in instituting any physical examination whatever until long after the development of pronounced constitutional and pulmonary impairment; (2) failure to examine upon the bare skin, the presence of clothing effectually preventing any approach to accurate results; (3) neglect to examine the entire chest; the bases, interscapular spaces, and axillary regions being frequently overlooked. He deplores particularly the existence of: (1) Erroneous conceptions concerning the significance of the absence of percussion-dulness at the apices, an active process often being capable of recognition by auscultation considerably before the evidences of consolidation are apparent; (2) the non-recognition, in the absence of râles, of the various modifications in disease of the normal respiratory sounds; (3) Inaccurate interpretation of localized diminished intensity of auscultatory sounds, elevation of pitch, harshness of quality, and prolongation of expiration. He severely criticises: (1) Failure to utilize cough preceding forced inspiration in eliciting the presence of slight moisture in the finer tubes; (2) the non-appreciation of the almost pathognomonic significance of a circumscribed bronchiolitis, even in the absence of dulness or other auscultatory signs.

**Chronic Urticaria.**—Dr. Karl Kreibich (*Deutsche Medizinal-Zeitung*, October 2d) says that urticaria is classified as a chronic skin affection when exacerbations of wheals occur repeatedly for a long time, thus producing what are known as urticaria recidiva and urticaria perstans. The urticaria recidiva of long duration seldom occurs in the form of large, intensely red wheals which rapidly disappear as in acute urticaria. Generally it is of another type, the lesions appearing as small, pale-red or dirty yellowish-red wheals, which soon become scratched and covered with a small blood crust; when the latter falls off there is left a yellowish-brown pigmentation. This disease is not identical with lichen urticatus (erythema papulatum), which has its typical seat on the extensor surfaces and is often accompanied by cinnamon-colored erythematous spots. In urticaria perstans there may

exist either urticarial wheals of weeks' duration (urticaria perstans simplex), or there appear pea-sized, hard, not sharply defined, pale-red, persistent papules, which consist anatomically of an infiltration of the cutis with leucocytes. If in addition to the latter there occurs an epithelial hyperplasia, then the papules and tubercles assume a warty appearance (urticaria perstans verrucosa).

**Echinococcus of Both Lungs and of the Liver.**—Steiner (*Berliner klinische Wochenschrift*, September 25, 1899) has reported the case of a girl, twenty years old, who for six months had noticed an induration in the region of the liver. She complained of dyspnœa, pain in the right side, cough, and expectoration. The anterior wall of the thorax was unduly convex. Dulness was detected posteriorly on the left side from the seventh dorsal vertebra downward, and in this area the vocal fremitus and the respiratory murmur were much enfeebled. In the same area, in the intervals of breathing, a blowing murmur synchronous with the systole was audible. The breathing was enfeebled at the base of the right chest. The heart was displaced somewhat downward and to the right. The first sound was dull, the second valvular. In close proximity to the mouth a loud, vibratile, sometimes whistling murmur could be heard, and with greater intensity when the mouth was open. The patient was herself conscious of this murmur, which could be heard also in the left lateral fossa of the neck, but not over the thorax. The left lobe of the liver extended to the level of the umbilicus. Its surface was nodular, but no thrill was appreciable. The right lobe of the liver was but little enlarged. The patient lived in the country with her father, and the household included two dogs. On exploratory puncture of the left lung over the area of dulness at the lower border of the eighth rib, echinococcus fluid was evacuated. The diagnosis being thus established, operation was decided upon, and the echinococcus of the left lung and of the liver was removed at one sitting. When the abdomen was opened, a large echinococcus sac was found in the left lobe of the liver, and which was attached by sutures to the abdominal wall in order to close off the peritoneal cavity. An incision was then made and a large amount of fluid evacuated. A communication with the subphrenic space was further found to exist. The entire wound cavity was now packed with gauze. Next, after resection of the seventh and eighth ribs on the left side, and suture of the pleura to the lung, between 300 and 400 c.c. of fluid was evacuated from an echinococcus cyst. This wound also was packed. After the lapse of some six weeks signs of involvement of the lower portion of the right lung became increasingly conspicuous, and exploratory puncture evacuated echinococcus fluid. Two weeks later between 15 and 20 c.c. of clear fluid were evacuated, and threatening symptoms followed, with the development of broncho-pneumonia. The patient was for some time quite ill, but she eventually recovered, gaining considerably in weight.

**The Study of the Nerve-Cell Changes of the Spinal Cord in Cases of Cerebro-Spinal Meningitis.**—Dr. Sidney I. Schwab, before the St. Louis Biological Society, June 13, 1899, read a paper on this subject, and believed the following conclusions seemed to be justified from the facts observed: (1) In epidemic cerebro-spinal meningitis we have to do with a process which affects the sensory cells. (2) The Clarke's system of cells shows greater tendency to the disease than any other system of cells. (3) This tendency cannot be explained by means of the effect of the mechanical pressure of the exudate. (4) The degeneration of these cells is caused by a toxin which originates from the specific agent of the disease, the micrococcus intracellularis meningitidis of Weichselbaum, which has a special affinity, first, for all sensory cells; secondly, particularly for the cells of Clarke's column, therein showing possible specific action toward these cells. (5) If the exudate does exert any pressure it is to be regarded as affecting the resistance of the cells which come within this line of its force, and the cells so acted upon react more easily to the toxic material than the others.

**Typhoid Fever of Unusual Duration, with Successful Operation for Perforation of the Cæcum and Peritonitis.**—Hawkins and Thurston (*Lancet*, October 14, 1899, p. 1004) report the case of a girl eleven years old, who had had some shivering five days before coming under observation, followed by a feeling of heat, with pains in the limbs, although she had been ailing for some days before this, with diarrhœa and a little nocturnal delirium. On admission the child appeared well nourished, with flushed cheeks. She was brighter and more cheerful than is commonly the case at the tenth day of typhoid fever. Widal's test yielded a negative reaction, and the diazo reaction was doubtful. The tongue, though not dry, was thickly furred, the abdomen was somewhat distended, and the spleen could be felt. No characteristic spots were seen. During the first five days of observation the temperature remained steady at between 102° and 103° F. It then began to fall, with a wide daily variation, but at the close of the second week the fall ceased and a fresh accession of fever set in. Widal's test still yielded a negative result. After a month the patient was in good condition, the bowels exhibiting a tendency toward constipation throughout, and enemata being necessary from time to time. The temperature, which often reached 104° F., and sometimes 105° F., showed a wide daily oscillation. The spleen was considerably enlarged; one doubtful spot was noted. The abdomen was slightly distended, and the tongue was thickly furred, but not dry. The pulse varied between 100 and 114. The patient was taking milk well, and no stimulant had thus far been necessary. Early in the morning on the forty-first day of the illness the patient was seized with pains in the abdomen, and was sick, while the bowels acted freely. The pulse was 108 and the temperature 103.4° F. Nothing abnormal was found on examination of the abdomen, and the patient fell asleep. After an interval of two and a half hours another attack of pain occurred, but there was no alteration in the condition of the abdomen beyond slight impairment of the respiratory movement, and there was no diminution in the area of hepatic dulness. Hot fomentations afforded great relief, but the pain soon recurred, the pulse rising to 120 and the temperature to 105° F. At midday vomiting set in; a little dulness appeared in the flanks, and the face began to alter. The pulse was 140, and the abdomen was more rigid, though not distended, while the hepatic dulness remained unaltered. Some delay was encountered in securing permission to operate, and this was done some fifteen hours after the occurrence of perforation. The patient was anæsthetized with chloroform, and a four-inch incision was made in the middle line below the umbilicus. On opening the peritoneal cavity a large quantity of seropurulent lymph escaped which had a faint fecal odor. The cæcum was brought to the surface with the idea of using it as a guide to the lower end of the ileum, the most frequent site of perforation, and a perforation was at once found on the anterior cæcal wall. The orifice was about one-eighth of an inch in diameter. It was surrounded by a zone of indurated tissue, and through it a little gas was escaping. A thin layer from the margin of the aperture was excised, and this

was then closed by a row of Lembert sutures, which produced good inversion of the edges, and a few reinforcing sutures were also introduced. The abdomen was thoroughly irrigated with sterilized water, and was then mopped out with marine sponges, especial care being taken to cleanse the pelvis and lumbar hollows. The intestines were slightly distended, but no thinned areas were seen, and it was not thought advisable to prolong the operation by a lengthy search for a possible second perforation. A rubber drainage-tube was inserted into the pelvis, and a similar one into the right loin, and a gauze-like drain was passed superficially upward. The wound was closed with silkworm-gut sutures. The duration of the operation was twenty-five minutes. The pulse failed slightly toward the end. The patient was given morphine subcutaneously and she slept throughout the night. Nutrient enemata, each containing a drachm of brandy, were administered every two hours. On the following day the general aspect of the patient appeared fairly good. The abdomen was flat and resonant, and respiratory movement seemed unimpaired. A fair quantity of seropurulent fluid had escaped and a gauze drain was introduced down the pelvic tube. Small quantities of milk and beef tea were given alternately by the mouth. On the following day the discharge was much less in amount, but more purulent and offensive. The abdomen remained unchanged, but the patient often vomited twice after taking milk. Two days later she suffered from paroxysmal attacks of abdominal pain, and the abdomen became somewhat distended above the umbilicus and moved less freely below. The amount of discharge was unaltered. The gauze drain was removed, the lumbar drainage tube was replaced by a strip of gauze, and the pelvic tube was changed for a smaller one. On the next day the abdominal pain became severe. The child was frequently sick; the abdomen became distended and tender; the discharge was serous and increased in amount; the pulse rate rose to 146; the bowels acted five times; and her general condition was grave. On two occasions 60 c.c. of decinormal saline solution were injected beneath the skin. By the following day the general and local conditions exhibited improvement. The pelvic tube was replaced by a gauze drain. A few days later all anxiety with regard to the peritoneal trouble was at an end. Rectal feeling was entirely discontinued, sufficient food being taken by the mouth. A parotid bubo now made its appearance on the right side, and an abscess developed in the buttock at the site of an injection of saline fluid. The abdominal wound gaped widely, and showed no sign of repair. The temperature was steady between 102° and 103° F., and the bowels were loose. After eight days the bubo and the abscess in the buttock were opened, and the abdominal wound resutured. Six days later the patient complained of pain and tenderness in the right femur, but no swelling could be detected. Two days subsequently bilateral otitis media supervened. After three days the pain in the thigh had ceased, but there was effusion in the left knee-joint, with pain and tenderness, followed on the next day by a similar condition of the right knee. A daily dose of 5 c.c. of antistreptococcic serum was injected for the next eleven days, and during this period there was great improvement in the general and local condition. The bubo and the abscess disappeared; the abdominal wound began to heal; the knee-jerks became normal; the discharge from the ears gradually ceased, and the temperature fell to normal. The knee-trouble was probably of septic origin, and was not an instance of specific typhoid arthritis. For twenty-three days the patient now slowly improved, and there was no ground for anxiety. The temperature, however, though always normal at some time of the day, was generally 99° or 100° F. in the evening, and the tongue never became quite clean. After the lapse of about three months a definite relapse set in, which lasted fourteen days. Widal's test now for the first time yielded a positive reaction, and the spleen again became enlarged. The abdomen was somewhat distended, the tongue was furred, and the temperature at the height of the relapse reached to from 103° to 104° F. A year after the onset of the illness the patient was robust and well, and presented no sign of abdominal disease.

**Treatment of Tuberculosis by the Landerer Method.**—At the meeting of the Association Française pour l'Avancement des Sciences, on September 14th–21st, Dr. Samuel Bernheim described this method, now in use for several years, which consists in injecting into the veins or into the muscles a solution of cinnamate of sodium. The conclusions which Landerer and Bernheim draw are: (1) Cinnamic acid and its compounds may be considered as absolutely inoffensive products, exerting no action upon the healthy organism in man. These agents have also no influence upon other diseases. (2) Their action is shown by the following manifestation: from the very first injection a hyperleucocytosis is established, and we find in the circulation especially a large number of polynuclear leucocytes and eosinophiles. Even around tuberculous foci an inflammatory process is set up which terminates in the production of connective tissue and of young vessels. This sclerous transformation extends by radiation through the tubercles, which soon present the appearance of cicatricial tissue. (3) These injections of cinnamate of sodium, which may be either intramuscular or intravenous, should always be begun with very small doses, starting with 1 mgm. and going up to 50 mgm., which dose need not be exceeded. We are guided in the increase of the dose by the patient's general condition, the temperature, the hæmoptysis, and finally the leucocytosis. According to the mildness or severity of the case the method is continued a longer or shorter time. We must, however, reckon upon a minimum of three months, and it may reach a year's duration. The patient should meanwhile be placed under the best hygienic conditions. (4) The authors have collected two hundred and eighty-four cases representing different forms of tuberculosis thus treated with good effects, often with success.—*La Méd. Moderne*, September 20th.

**Erythema Nodosum in the Course of Puerperal Infection.**—Dr. Brodier, writing in *La Médecine Moderne*, September 20th, refers to erythema nodosum in streptococcic septicæmia, of which he reported an instance in 1893. He now relates the history of a domestic, twenty years old, who aborted after an injury in the sixth month. Three days later there was severe pain in both legs, and the antero-external area of the left leg was the seat of an erythematous patch. A similar patch appeared within a few days upon the opposite leg. On the sixth day after confinement the diagnosis was undoubted. There was an abundant purulent discharge from the vagina, and there were superficial ulcerations about the vulva as though due to ruptured vesicles. The evening temperature was 39.6° C. The nodes upon the legs went through the typical course, but on the seventeenth day there were chills and a fever of 40° C. with abdominal tenderness, and the vaginal discharge began again; a swelling occurred in the popliteal space, and the nodes again became bright red, increased in size, and soon showed fluctuation. Puncture of the lesions resulted in the discharge of an abundance of thick, blood-stained pus. The fever persisted, and a large phlegmon of the left iliac fossa developed, and death

occurred on the fifty-fourth day from the abortion. Examination revealed nothing in the abscesses of the legs excepting streptococci. The author, therefore, believes that erythema nodosum may be the first manifestation of a septicæmia ending in death. [The term employed would here seem to be a misnomer, since erythema nodosum proper never results in suppuration.—Ed.]

**Dermatomyositis.**—Dr. Oppenheim (*Berlin. klin. Wochensch.*, September 11th) describes this affection as observed in a child nine years of age. There were pains in groups of muscles, difficulty of movement, redness and swelling in certain regions, pain about the pharynx and mouth, with difficulty in swallowing. There was also a certain amount of atrophy and paralysis in some muscles, which were hard and contracted. Some skin areas were red and appeared infiltrated. This rare affection may be confounded with muscular dystrophy or subacute rheumatism. The lesion is an infiltration of muscular tissue by small cells, enlargement of the internal perimysium, and partial destruction of muscular fibres.

**Treatment of Gonorrhœal Salpingitis.**—J. W. Taylor (*British Gynæcological Journal*, August) prepared a short abstract of the propositions he was disposed to maintain, as follows: (1) That a large proportion of women who are suffering from tubal disease have been, at some time or other, exposed to the infection of syphilis as well as of gonorrhœa; that these undoubtedly show marked improvement after a prolonged course of mercury and iodides, and in the course of this treatment, unless acute pyosalpingitis intervenes (in which medicine is useless), it is the rule rather than the exception for all gross physical signs of disease slowly and permanently to disappear. (2) That in many cases in which there is no history of syphilis, including cases in which there is an unmistakable history of gonorrhœa pure and simple as the sole cause and starting-point of tubal disease, the patients do similarly improve and get permanently well under the same course of treatment, provided always that the disease stops short of acute pyosalpinx. (3) That acute pyosalpinx is peculiarly liable to occur in the first place on the left side of the body, and its severity is probably due to secondary infection from the rectum; that cases of pyosalpinx, whenever possible, should be treated by free incision of the posterior vaginal fornix, by thorough exploration and emptying of all pus cavities from the pouch of Douglas, and by iodoform-gauze drainage; that this is far preferable to the older operations of removal of the appendages, which is not only much more dangerous, but is peculiarly liable to be followed by fecal fistula, an operation sequel sometimes worse than death itself. (4) That such cases of mixed infection and acute suppuration treated by operative evacuation do sometimes not only result in recovery, but remain permanently well without further treatment, the acuteness of the inflammation appearing to terminate the process of infection. In other cases, recovery is not so complete, and relapses are met with, and these cases should be followed up by a course of specific treatment, the beneficial results of this being often immediately manifest when the wound tissues are unhealthy, and the healing is delayed. (5) That occlusion of the tubes and peritubal adhesions consequent on gonorrhœal adhesions have no direct specific causation, and must be regarded rather as secondary mechanical results of the local peritonitis which has been caused by salpingitis. Their absorption and disappearance will not, therefore, be necessarily secured by cure of a gonorrhœa, and sterility may persist although the gonorrhœa is entirely eradicated from the system. (6) That in gonorrhœa of the pelvis there will probably remain a residuum of intractable cases, particularly cases of complication with other diseases, such as fibroids of the uterus; that in these cases operative removal of the organs affected will still be required, and that vaginal hysterectomy whenever possible, with or without extirpation of the uterine appendages, is not only the most rational operation in theory, but is productive of the best final results.

**Formalin in Tuberculosis.**—In joint tuberculosis and tuberculous abscesses Hahn (*Centralblatt für Chirurg.*) advises withdrawing the pus by aspiration and then injecting boric-acid solution, which is in turn withdrawn. Formalin-glycerin solution in the strength of one per cent. is then thrown in, and in the case of a joint the limb is fixed to a splint. There are fever, pain, and an increase in the fluid, but usually within two weeks absorption occurs, and recovery frequently follows.

**A New Granule Found in the Blood and Excretions.**—In the large round cells from the sputum, from purulent serous exudates of pleurisy and pericarditis, in ordinary pus, and in new non-inflammatory tissues, L. Grünewald, of Munich (*Centralblatt f. innere Medicin*, 1899, No. 30, p. 777) has found a new type of granule which he designates as the hypeosinophile granule. This stains by the ordinary eosin method a deep red, but the color is taken out by the application of either acids or alkalies; with the Ehrlich triacid mixture, the granules stain red like fuchsin, instead of orange as do the ordinary eosinophile granules. Preparations are best fixed by ordinary drying in the air or by slight heating. These granules are also found in the normal blood, usually situated in the mononuclear or polynuclear cells.

**Notes on Some of the Experiments on the Cure of Anthrax.**—J. McGarvie Smith and J. A. Gunn (*Australasian Medical Gazette*, August) state that the experiments, so far as they have gone, seem to indicate (1) That injection within eight hours of infection of an adequate dose of serum of an immune sheep—that is, one that has been vaccinated against anthrax, and the immunity of which has been subsequently proven by its perfect resistance to the injection of the virulent germ—is not capable of effecting a cure in sheep. (2) That the minimum dose requisite for sheep is 40 c.c. if used four hours after the injection of 0.1 c.c. of a cultivation of virulent anthrax, 150 c.c. if used six hours afterward, and 250 c.c. if used eight hours afterward. (3) That, if the initial dose is too small, after-injections are of little value unless used frequently, and in excessive quantities. (4) That, as the injection of large quantities of the serum appear to have no ill effect on the animal, the dose quoted above might with advantage be largely increased.

**Primary Epithelioma of the Uvula and Soft Palate.**—An instance of epithelial cancer, starting in the uvula, was published by Dr. Walker Downie in the January number of the *Scottish Medical and Surgical Journal*. In the March number of the same publication Dr. Lennox Browne reports a second case of this rare origin, and adds to the literature an equally rare case in which epithelioma was limited to the soft palate without involving the uvula or tonsil. There seems to be no good reason why these parts should escape malignant involvement, still but few instances have been recorded. The uvula case was operated upon, but the patient survived only nineteen months. Microscopical drawings accompany the article. In the second case, a man aged fifty-two years, had first experienced pain in swallowing, two months before. A small warty growth was seen at the free border of the left anterior faucial arch. A portion was removed, confirming the diagnosis, but the patient would not consent to operation.

# MEDICAL RECORD:

## INFLUENZA IN THE UNITED STATES.

IN the recent bulletin of the department of health of Chicago are published the mortality statistics of influenza and its complications. It appears that since the last great pandemic of influenza, which occurred in Chicago as the epidemic of 1891–92, there has been no period altogether free from the disease, and it would seem to have become permanently domesticated. In 1891 there were 336 deaths from influenza reported to the department; in 1892 there were 103; 88 in 1893; 51 in 1894; 165 in 1895; 17 in 1896; 15 in 1897; 281 in 1898; and 304 up to the close of July, 1899.

The bulletin, commenting upon this state of affairs, says: "While these figures are not in themselves very alarming, they have a serious significance for the student and worker in preventive medicine. It is true that the influenza epidemic of 1891 added less than one and a quarter per cent. to the deaths from all other causes, and the 304 influenza deaths during the first six months of this year are only two and a quarter per cent. of the total deaths from all causes. But the indirect results of the epidemic diseases swelled the total mortality rate by seventeen per cent. over the average mortality rate of the previous five years during which there was no influenza. The increase of the death rate this year is not so marked, but it is still more than fourteen per cent. greater than the average of the previous five years, the lesser comparative increase being fairly attributable to the prevalence of influenza, in a minor degree, during the previous five-year period."

The experience of Chicago is similar in a greater or less degrees to other large centres of population in which influenza has set its foot. Dr. Foster Palmer, writing on the prevalence of influenza in the different countries of the world, says that although the epidemic respects neither race nor country, we find that Russia, France, and the United States suffered in far greater proportions than Great Britain. Some want of balance in the organic functions must be the cause of this excessive receptivity, but what the special condition is, it is hard to say, for those three nations have little in common. Ethnical idiosyncrasy may account for it in the case of Russia and France, but the inhabitants of New York, who are for the most part of the same race and presumably of similar constitution, also suffered far more severely than did the inhabitants of Great Britain. "For some reason, therefore, it would seem that men of the English race in America have less resisting-power than in England. This is quite consistent with the history of our race in that continent, which, although in some of the wilder prairie regions it has attained a high pitch of strength and cultivation of the senses, has in many parts, especially in the towns, undergone a certain degree of physical deterioration." With these conclusions of the English physician most American medical practitioners will take issue. Statistics do not show that even in the towns the death rate in the United States compares unfavorably on the whole with that of the towns in Great Britain, and where such is the case the cause is found in inferior sanitation and not the less resisting-power of the Americans. The greater mortality from influenza in this country is probably owing to the higher nervous organization of the inhabitants. Influenza is pre-eminently a disease affecting the nervous system, and given a people with highly strung nerves, it follows as a matter of course that they would suffer more than those of a phlegmatic temperament. The most valuable researches into the causation of influenza have been made by Dr. Wynkoop, who has succeeded by methods introduced by himself in bacterially verifying the presence of the influenza bacillus in a very large proportion of the cases diagnosed as such. The conclusions of Dr. Parsons, published in *The Lancet* in 1894, are that the epidemics come on at almost any time of the year, that they are not greatly influenced in their prevalence by the weather, but that their mortality is increased by cold weather; that an attack affords, if not complete protection against, at any rate a modification of, future attacks both in the individual and in the locality; that it affects different localities with different degrees of severity, its relative fatality depending chiefly on the average of the population, being most fatal to quite young infants and to old people. In fact, we can ascertain the number of fatal cases in proportion to the population, but not to the number of people attacked.

## THE BULLETS IN SOUTH AFRICA.

THE peace conference at The Hague does not seem to have effected much either in the prevention of war or in the interdiction of the use of the so-called inhuman weapons of war. True it is that notwithstanding the protests of the British delegates, backed up by the American peace commissioners, the much-talked-of "Dum-dum" bullet was by a majority of the members of the conference prohibited. It will be recollected that the question as to the inhumanity of the Dum-dum was first raised by Professor Bruns, who after experimenting with them on dead bodies declared that the results of their contact was fearful, and could not be exaggerated. The answer made to this charge by British army surgeons was that experiments on dead bodies were altogether misleading; that the Dum-dum was not explosive, but that its effects were much more

harmful than those of an ordinary bullet of the same bore; but at the same time the assertion was made that a bullet wound from the old-time Snider was much more destructive. However, this defence was of no avail, and the Dum-dum was ruled out of civilized warfare. The claim is now being made on the European continent, and especially in France, that the British are violating one of the provisions of the Hague conference by their use in South Africa of a bullet almost as destructive as the Dum-dum. The New York *Herald*, writing on the matter, thus describes the new British bullet: "It has a copper socket which contains a charge of smokeless powder, and at the end is a lead ball enclosed in a nickel envelope. Toward the head of the bullet there is a small opening in this envelope." The contention is that when this bullet touches a soft substance the opening is compressed, and the projectile is so enlarged that it mushrooms, and causes fearful wounds. Dr. Bruns has been experimenting with these bullets upon dead bodies, and declares that their effects are as bad as those of the Dum-dum. British experts, as before, point out that these experiments having been made upon dead bodies at short range, the conclusions deducted therefrom are of little value. The Boers are also accused of using in battle the half-mantle game bullets, which expand at exit, and make terrible wounds. Objection has been brought against the shells loaded with lyddite, which were fired with such surprising precision by the British sailors at Ladysmith upon the Boers, and which are reported to have caused fearful carnage among them. General Joubert protested to General White against them, but in this instance, at any rate, the British are clearly acting in accord with the provisions of the Hague conference, as no mention was made with respect to the description of explosive to be used within a shell. After all, the main object in war is to disable or kill the enemy, and if it is found that an ordinary bullet from a small bore will not do this, one can scarcely blame either Britisher or Boer from using one that will guarantee this result. The same remark applies to shells. Nevertheless, if the fact can be plainly proven that either side is using bullets or explosives that contravene the decisions of the Hague conference, there would appear to be excellent reasons for neutral nations to take steps to insist upon the belligerents obeying these rulings. One feature of the present war is particularly worthy of notice, that the treatment of the wounded enemy has been characterized by the greatest humanity, and reflects credit on the leaders of both forces.

---

**A Patient Jumps through a Hospital Window.**—A young woman was found one evening last week trying to break her skull with a paving stone, and a policeman took her to the J. Hood Wright Memorial Hospital. The next day she broke away from her attendants and leaped through a plate-glass window to the ground below. The ward was in the second story, and the fall did not kill the woman, but broke her thigh and caused many contusions.

## THE "KISSING BUG" AND SPIDERS.

L. O. Howard, chief of the division of entomology of the United States department of agriculture, in a paper on the above subject read before the American Association for the Advancement of Science at Columbus, shows that the "kissing bugs" and death-dealing spiders, concerning which so much was written in the yellow journals during this summer, chiefly exist in the heated imagination of hysterical women, and the cases recorded are reported for the sake of sensation by mongering reporters. Mr. Howard gives a most interesting account of those spiders and insects whose bites are troublesome, but proves by most reliable testimony that their death-bearing qualities are non-existent. He concludes his article with these words: "Specimens of C. sanguineus received in July, 1899, from Marysville, Miss., were accompanied by the statement—which is appropriate in view of the fact that the newspapers have insisted that the 'kissing bug' prefers the lip—that a friend of the writer was bitten on the lip, and that the effect was a burning pain, intense itching, and much swelling. The writer of the letter had been bitten upon the leg and arm, and his brother was bitten upon both feet and legs, and on the arm, the symptoms being the same in all cases. The writer's conclusions are that a puncture by any one insect may be, and frequently has been, mistaken for a spider's bite, and that nearly all reported spider-bite cases have had in reality this cause; that the so-called 'kissing bug' scare has been based upon certain undoubted cases of the bite of one or the other of them, but that other bites including mosquitoes, with hysterical and nervous symptoms produced by the newspaper accounts, have aided in the general alarm."

---

## THE ILL-PAID MEDICAL MAN.

The English *Spectator*, in one of its recent issues, has been taking up the cudgels on behalf of the underpaid and ill-treated medical man, and explains, to its own satisfaction at least, why this is the case. There has been of late much discussion in Great Britain as to the inferior class of men—that is, in a social sense—who enter the medical profession in that country. We fail to see why a man who has not been educated in one of the high-class schools—provided that he has received a sound education—should not be as successful and as able a medical practitioner as one who has had perhaps $1,000 or $1,500 a year spent on his schooling. In this country at any rate the opinion prevails that the boy who has been compelled to fight his way, and has learned to overcome difficulties in the bitter school of adversity, is more likely to make a name for himself and prosper, than he whose path has been strewn with rose-leaves. Perhaps for a practice among what is termed in Great Britain the upper classes, a certain amount of culture and "*savoir faire*" is an aid to success, but on the other hand some of the most distinguished physicians have been by no means remarkable for these acquirements. However, with the *Spectator's* view that doctors are inadequately

remunerated no one will disagree, and if that journal can suggest an effectual remedy for this disagreeable state of things the physicians throughout the United Kingdom and America will be greatly beholden to it. With respect to the unsatisfactory pecuniary position of medical practitioners, the *Spectator* says: "That doctors on the outskirts of cities, and too many country doctors, are infamously paid we readily and heartily admit, but one main reason of that is a certain want of consideration in the social sense which is in consequence of the ancient tradition that they were not quite gentlemen. No idea could, as regards the majority, be now more false, and it is rapidly dying away, but the doctor remains the only man who is habitually swindled, whose charges excite a preposterous amount of annoyance, and who is put upon by "clubs" in a way which, if they tried it upon tradesmen, would produce an angry strike." The *Spectator* concludes with these words: "We want the doctors even in the slums to be educated as barristers, as devoted as the clergy, and as well paid as publicans [saloon-keepers]; and if the profession will but struggle for that ideal it will come." In Great Britain, as in this country, it is the sharp competition, together with the lack of cohesion among medical men, that renders their lot perhaps on the whole less desirable than that of members of the other professions. Much may be effected by loyally working together. Nevertheless it is to be feared that the day is still far distant—in fact the prospect is too dazzling to be anticipated with hope—when medical men will be paid as well as saloon-keepers. We must be moderate in our desires.

## NURSING IN VIENNA.

THE news that cases of bubonic plague had occurred in the Allgemeines Krankenhaus at Vienna, through inoculation by bacilli collected there for experiment, attracted at the time universal attention to that institution. The fact has since been brought to light that the unfortunate accident happened owing to the careless manner in which the plague germs were guarded. It is stated that the porter who had charge of the bacilli was addicted to drink, and that the nurse who became inoculated with the disease had been a parlor-maid before she entered the institution. In the *Nineteenth Century* for October, Miss O'Connor Eccles gives a description of her visit to the Allgemeines Krankenhaus, and records her impressions of the way in which that vast establishment is conducted. Miss Eccles concerned herself principally with the methods of nursing in vogue there, and has no hesitation in declaring that its condition is scandalous. She says: "The nurses are recruited from the lowest class of domestic servants, women who because of incapacity, increasing years, or doubtful character find it difficult to get a situation elsewhere. Many look as if they had been accustomed to field-work. They come in for a time to suit their own convenience, fulfil or neglect their duties as the case may be, and when anything better offers drift out again. Training properly so called they get little except in the obstetric wards. Whatever they learn they pick up in haphazard fashion." Vienna as a school of medicine has a reputation second to none, but it seems that its fame has been gained at the expense of the patient. The difference between an American or British and Viennese hospitals is that in the hospitals of the first-named countries the care of the patient is the chief object, and the main efforts are directed toward relieving or curing him of his malady. The advancement of medical knowledge takes the second place. In Vienna the reverse is the case. The hospital there is in the first instance a medical school. The fate of the patient is little considered, and it is a matter of more or less indifference to the doctor whether the sick person is relieved or cured, so long as he is an interesting subject for experiment, and is likely to be the means of furthering the progress of medical science, and incidentally contributing to the glory of the school and of its individual members. The increase of medical knowledge is undoubtedly of benefit to humanity at large, but if all that Miss Eccles relates of the Allgemeines Krankenhaus and its management be true, this may be bought at too dear a price. The American interpretation of a hospital as an institution founded for the relief of suffering will rather commend itself to the inhabitants of this country.

## News of the Week.

**Hospital Thief Arrested.** — The thief who went through the Orange Memorial Hospital and the Orange Training-School for Nurses last week, under pretense of repairing the electric-light wires, has been arrested in Reading, Pa., where he attempted to work the same game.

**Transport Scandals in the Pacific.**—Those who remember the deplorable lack of medical service on several of the army transports bringing the sick and wounded to this port from Cuba in the summer of 1898, and the lame excuses offered by those who should have been held accountable for the occurrence, will not be surprised to learn of similar happenings on transports from the Philippines. According to the San Francisco *Examiner*, a most sensational report by a military board of inquiry has just been forwarded to Washington from the headquarters of Major-General Shafter. The document contains the severest kind of criticism of the methods employed by officers in charge of the sick soldiers who returned from the Philippines on the transports *Tartar* and *Newport* on October 10th. Upon the surgeon of the Twentieth Kansas Volunteers, who came back on the *Tartar*, the heaviest censure is laid. The colonel of the same regiment, who commanded the ship, is indirectly referred to, and many other officers receive a hard measure of criticism. The board of inquiry was appointed by General Shafter two weeks ago, at the suggestion of Colonel Alfred C. Girard, chief surgeon in the general hospital at the Presidio. Colonel Girard's desire for an investigation was occasioned by the de-

plorable condition in which he found the sick men from the transports *Tartar* and *Newport*. There are about forty of them, and nearly all were suffering from dysentery. Three men who came on those transports died a few days after their arrival.

**University of Virginia Hospital.**—A new hospital is to be built on the grounds of the University of Virginia, at a cost of $25,000, by the medical faculty of the university.

**Diphtheria** of a malignant type has broken out at Herkimer, N. Y., and an appeal has been made to the State board of health for assistance in stamping it out. It is thought that the disease was spread in the first instance through infection of school-books.

**Emigrant Quarantine in Europe.**—Dr. A. H. Doty, health officer of the port of New York, who recently went abroad in order to make arrangements for the detention, at the port of sailing, of emigrants from Russia until the period of incubation of smallpox had passed, after having visited Hamburg and Bremen and conferred with the steamship agents and port authorities, has gone to Russia in order to secure the co-operation of the frontier officers in that country if possible.

**The Effects of Modern Small Arms.**—Dr. Charles B. Nancrede, writing on the effects of modern small-arm projectiles from his experience during the Cuban war, says: "The 'explosive effects' of modern balls, at the distance at which most must strike in an actual engagement, will not produce such destruction of bone as often to demand amputation, if asepsis can be secured; hence, removal of limbs for extensive fracturing of the long bones was almost unknown. Indeed, I have seen perforation of a tibia without loss of continuity, notching of the condyloid ridge of the humerus with not even a fissure of the shaft, while other bones were merely guttered."

**The Sanatorium for Consumptive Soldiers** at Fort Bayard, N. M., was opened recently. Three of the barracks buildings and most of the quarters for officers are in use. The buildings are of brick, have wide verandas, an amusement room with billiard and card tables, and a library, with periodicals and newspapers. There are accommodations for one hundred patients, and next year room will be made for two hundred more. The invalids are required to spend the greater part of the day in the open air. Twenty patients had already arrived, and many more are on the way. The sanatorium is under the care of Dr. Daniel M. Appel, surgeon United States army, who has a staff of three nurses and thirteen assistants.

**Nursing the Wounded at Mafeking.**—In Mafeking, which, as is well known, is being so gallantly defended by Colonel Baden-Powell and his handful of British against a large Boer force, is a large Roman Catholic convent. The sisters of the convent, with that devotion to duty which has ever been one of the most striking characteristics of those women wedded to the Roman Catholic religion, although granted permission to leave the beleaguered town by the Roman Catholic bishop, have all elected to stay and render assistance in nursing the wounded. A number of ladies in Mafeking have also volunteered to remain and act as nurses.

**A Large Purchase of Quinine.**—The government recently placed with a wholesale drug house an order for 7,500,000 grains of quinine in five thousand bottles, each bottle containing five hundred three-grain pills. The bids ranged from 93 cents a bottle up to $1.30, the contract being awarded to the lowest bidder.

**Hospital Ships for the Boer War.**—The Princess of Wales has placed at the disposal of the Red Cross Society a considerable sum of money—the remainder of a fund collected at the time of the Soudan campaign in 1885—for the equipment of a hospital ship. The committee is making arrangements to secure the British steamer *Midnight Sun*, which will be renamed *Princess of Wales*. Her Royal Highness will personally contribute £1,000 ($5,000) toward the equipment. The movement recently started in London to raise a fund to equip the *Maine* of the Atlantic Transport line as an American hospital ship for service on the South African coast is meeting with great success. The treasurer had received up to November 3d the sum of £10,000 ($50,000) from Americans in England and this country in behalf of the fund.

**Medical and Nursing Staff of the British Army.**—The medical and nursing staff of the British army of invasion for South Africa, although the medical ranks have had to be reinforced by civil practitioners, would on the whole seem to be a strong one. The surgeon in chief, General T. D. Wilson, has seen service in various parts of the globe and is eminently fitted for the post he has been selected to fill. It is said too that Sir William MacCormac will proceed to the seat of war and aid with his valuable advice. Fortunately the climate of Natal, and in fact of the greater part of South Africa, is healthy, so that there will not be much cause to fear those complications of fever which are generally in war far more destructive to human life than the bullets of the enemy.

**English Medical Men in the Transvaal.**—The Boers, says *The Medical Press*, are no respecters of persons, and their treatment of medical practitioners, with whom they may happen to have a grievance, leaves a good deal to be desired, as the following example will show: A practitioner was summoned to attend the little child of a Boer, but refused to respond to the summons, inasmuch as another medical man had charge of the case. In consequence of this refusal the Boer lodged a complaint against the practitioner at the next meeting of the local governing-board of the district. Accordingly a resolution was passed by the latter pledging the members thereof to boycott the practitioner, and a young practitioner from a neighboring part was invited to settle in the district, and was promised the support of the local authorities. This perfectly unwarrantable step was taken merely because the medical man in question, by acting in accordance with professional usage, displeased a per-

son who was the patient of a confrère. Medical practice under such conditions could scarcely be enviable, but now the time seems to have arrived when old scores will have an opportunity of being paid off.

**The New York State Association of Railway Surgeons.**—The ninth annual meeting of this association will be held at the Academy of Medicine in this city on Thursday, November 16, 1899. The special topic for discussion will be "The Physical Fitness of Railway Employees." Papers will also be read by Dr. Robert T. Morris, on "Where Hydrogen Dioxide is Harmful"; by Dr. B. F. Curtis, on "Dislocation of the Shoulder with Fracture of the Neck of the Humerus"; by Dr. John L. Eddy, on "Emergent Surgery"; and one by Charles E. Townsend. The officers of the association are: *President*, Theodore D. Mills, of Middletown; *Vice-Presidents*, J. L. Eddy, of Olean, and G. N. Hall, of Binghamton; *Secretary*, C. B. Herrick, of Troy; *Treasurer*, H. P. Jack, of Canisteo.

**Boer Treachery.**—The following instance of Boer treachery was published as related by an English officer on the spot, in the *St. James's Gazette*. It appears that a civilian doctor was, with a surgeon major, despatched from Pretoria to the scene of the Brunkers Spruit massacre to succor the wounded prisoners. His uniform saved the military surgeon, but the other doctor, the Boers having decoyed him into a house on the pretence of giving him a drink of milk, was stripped to his nether garments and cowhided—yes, incredible as it may seem, actually cowhided—to within an inch of his life.

**Dr. Domingos Freire,** of Rio de Janeiro, is dead. He was one of the first to announce the discovery of the specific microbe of yellow fever, and he also made a prophylactic and curative serum for which he claimed great efficacy. Much heated controversy has arisen over his alleged discovery, and many most competent bacteriologists and students of yellow fever have denied the specificity of his microbe or the efficacy of his serum. Others, on the other hand, have asserted that his discoveries were of great value, and even that Sanarelli was indebted to him for his bacillus and serum. Dr. Freire was formerly professor of organic chemistry in the faculty of medicine in the University, and later director of the Bacteriological Institute at Rio.

**The Alvarenga Prize of the College of Physicians of Philadelphia** has been awarded to Dr. Robert L. Randolph, of Baltimore, Md., for his essay entitled: "The Regeneration of the Crystalline Lens—An Experimental Study." The next award of the Alvarenga prize, which is the income for one year of the bequest of the late Señor Alvarenga, and amounts to about $180, will be made on July 14, 1900, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1900. Each essay must be sent without signature, but must be plainly marked with a motto, and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

**Guarding against the Plague.**—Passed Assistant Surgeon James A. Nydegger and Assistant Surgeon John F. Anderson of the Marine-Hospital service have been ordered to Spain to assist the consuls at Cadiz and Barcelona to enforce the quarantine regulations of the Treasury Department regarding vessels bound for the United States. From these two ports, these officers will have surveillance over emigration from Spain and Portugal.

**A Memorial to the Late Dr. Rohé.**—The Maryland Public Health Association has voted to place a bronze portrait medallion in the Springfield Asylum for the Insane as a memorial to the late Dr. George H. Rohé, to whose labors the institution practically owes its existence. Some of the members of the memorial committee, however, prefer the hall of the Medical and Chirurgical Faculty as the place for the erection of the tablet, and it is possible that this will be finally selected.

**Trouble at a State Asylum.**—The board of managers of the State Custodial Asylum for Feeble-Minded Women, at a meeting held October 31st, passed a resolution asking for the resignation of Dr. Mary Alice Brownell, the resident physician. The reason given for this action is that there was trouble between the superintendent and Dr. Brownell. The latter, however, denies that there is any serious trouble between her and the superintendent, and declares that she will not resign until forced to do so by higher authority than the board of managers. Dr. Brownell is a graduate of the University of Michigan, and has been resident physician of the asylum for eight years.

**Yellow Fever.**—New cases of fever continue to be reported from Miami and Key West, but in other places in the South the epidemic has been extinguished by the frost. The embargo against the infected places has been raised, and interference with commerce and travel is at an end. The record of the epidemic at Jackson, Miss., is sixty cases and eleven deaths. At Key West there had been a total of twelve hundred and sixty cases and sixty-two deaths up to November 3d. In Miami, Fla., ten new cases were reported on November 2d and 3d. A man died of yellow fever on board the United States transport *Kilpatrick*, which arrived here last week from Havana. The yellow-fever statistics of Havana for October show that at the beginning of the month there were in the hospitals twelve patients who had been attacked by the disease in September. The new cases in October numbered 63; deaths, 25; recoveries, 26; under treatment, 24; Spanish cases, 36; deaths, 15; American cases, 20; deaths, 8. The total number of deaths for the year is 63. October was the worst month. The disease is

now decreasing. Dr. Herman Parker, surgeon of the Marine-Hospital service, stationed at Santiago, reported on November 4th that there had been no cases of yellow fever in that city for three weeks.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending November 3, 1899. October 27th.—Assistant Surgeon R. Spear detached from the *New York*, ordered home, and granted sick leave for two months. November 2d.—Assistant Surgeon R. K. McClanahan detached from the Naval Hospital, Key West, Fla., and ordered home and granted sick leave for two months.

**Obituary Notes.**—Edward Bleecker, M.D., died at his home in Whitestone, Borough of Queens, on Sunday, November 5, 1899. He had been in failing health for several months, and finally succumbed to an attack of pneumonia. Dr. Bleecker was born in Albany January 9, 1844, where his father, William E. Bleecker, was a prominent merchant for many years. He was a direct descendant of Yan Yancy, first recorder and second mayor of Albany. After graduating from the old Albany Academy, he completed his academic studies at Burlington, N. J., and entered as a medical student at the Albany Medical College, but subsequently matriculated at the College of Physicians and Surgeons in New York, where he graduated in 1865. He immediately received an appointment in the Albany State hospital for wounded soldiers under Dr. Swainburne, where the foundation of his surgical skill was laid. When Dr. Swainburne was appointed health officer of New York, Dr. Bleecker came to Staten Island with him. In October, 1866, he married Miss Ellen H. Barton, of Philadelphia, and in 1868 settled in Whitestone. He succeeded almost immediately to a large practice among a wealthy clientèle, whose confidence and affection he enjoyed to the end. Dr. Bleecker was a factor of weight and influence in all the public affairs of the community, having for nearly a score of years held the office of president of its board of trustees as well as of its board of education. In co-operation with Captain I. J. Meritt, he was a prime mover in all the public improvements which Whitestone enjoys. Especially was this true of the various measures for water supply, improved roads, and school administration, which were carried to a successful issue largely through his foresight and wise guidance. He was president of the water board and the leading spirit in the construction of artesian wells, from which Whitestone derives an unequalled and unfailing supply of pure water. But it is as a surgeon that Dr. Bleecker probably will be best remembered. His work in the Flushing Hospital was of a high order of excellence. Always resourceful and courageous as an operator, he shrank from no responsibility which seemed likely to enhance his patient's chances of recovery, yet he had rare qualities of conservatism which protected his patients from an operation merely for the sake of operating. He was for some years president of the board of trustees and of the medical staff of the Flushing Hospital, and was the chosen almoner of large sums of money which wealthy personal friends from time to time gave to the hospital for new buildings and equipment. He was also a fellow of the New York Academy of Medicine, a member of the Queens County Medical Society, of the Associated Physicians of Long Island, and of the Medical Association of the Greater City of New York. Dr. Bleecker's rare social qualities, genial temperament, and ready accessibility endeared him peculiarly to a wide circle of friends. Among rich and poor alike for over thirty years he had been a constant and unfailing resource in trouble and affliction. His strong personal individuality and identification with all that was progressive and best in the community awaken a sense of irreparable loss not alone among his professional associates but wherever his helpfulness and sympathies had comforted and relieved. Mrs. Bleecker, a daughter, Anna, and three sons, William, Rutgers, and Edward, survive him, all of whom reside in their home in Whitestone.—Dr. Luther Dana Woodbridge, professor of anatomy and physiology in Williams College, died suddenly of heart disease at Williamstown, Mass., on November 3d. He was born in Perth Amboy, N. J., December 27, 1850, and was graduated from Williams in the class of 1872 with the first philosophical oration. For two years he was a teacher at Roberts College, Constantinople, and then began the study of medicine, and was graduated from the College of Physicians and Surgeons of New York City, in the class of 1877, being one of the ten honor men. He served terms as interne at the Roosevelt and Chambers Street hospitals. After a year of study in the hospitals of Vienna and London he became assistant surgeon at the Manhattan Eye and Ear Hospital. From 1881 to 1884 he practised in New York City, and then went to Williams as professor of anatomy and physiology. Dr. Woodbridge was a member of the American Academy of Medicine, the American Medical Association, and the State Medical Society of Massachusetts, and was ex-president of the Berkshire Medical Society. He was also a lecturer on "The Nervous System and Its Diseases" in the Boston College of Physicians and Surgeons.—Dr. Charles Inslee Pardee died of heart disease on November 3d at his residence in this city. His death was wholly unexpected. Dr. Pardee was sixty-one years old. He served with distinction throughout the Civil War as a surgeon, and was a member of the Loyal Legion. He was for twenty-five years dean of the University Medical College. Dr. Pardee was graduated from the University of New York in the class of 1860. He was a member of the Academy of Medicine.—Dr. Charles H. Holzhausen died at his home in the city on November 5th, at the age of twenty-nine years. Death was due to typhoid fever with which he had been ill for about two weeks. He was a graduate of the Bellevue Hospital Medical College.—Dr. Samuel Q. Robinson, major and surgeon in the United States army, died at Hot Springs, Ark., on November 6th. He was born in Massachusetts, and was appointed an assistant surgeon on January 9, 1877, a captain assistant surgeon January 9, 1882, and a surgeon major May 2, 1896.

# Clinical Department.

## FRACTURE OF THE ARM IN A NEW-BORN CHILD.

By CHARLES H. HOLZHAUSEN, M.D.,
NEW YORK,
ASSISTANT SURGEON TO THE BELLEVUE HOSPITAL DISPENSARY.

On March 9, 1899, a male child was brought to the Bellevue Hospital dispensary by its grandmother, the child then being but one day old. The grandmother noticed, while bathing the child, that the right arm hung limp and helpless, and the child did not move it at all. On examination, I noticed that there was absence of swelling or ecchymoses, but found a fracture of the surgical neck of the humerus. The child was born, according to the grandmother's story, normally and without assistance. No physician or midwife was present because of the poverty of the parents. The fracture was treated the same as if it had occurred in an older child. In about three weeks there was union, and the child suffered no further incon nience.

352 West Twenty-first Street.

## STARVATION ŒDEMA.

By ANNIE H. PATTERSON, M.D.,
CHINKIANG, CHINA.

We have just passed through a famine season which brought to us a class of patients new to me, and I have not been able to find any literature on the subject.

The patients I speak of were ten in all, and had been eating wild plants, something like what we call "greens" in the South, with a very small percentage of grain. We named the affection "greens dropsy." The parts swollen were in the order named: hands, eyelids, face, scalp, and neck; and no other part of the body was swollen. They were all dispensary patients, and I failed to examine the urine. What they came for and the only symptoms complained of was the swelling. The first patient I saw was a girl of sixteen years; the eyelids were swollen beyond recognition, as were also the hands and neck. The mother said the girl had been in that condition only two days, and the swelling was beginning in herself also. I could detect a slight swelling of the eyelids and backs of the hands in the mother. I immediately thought there must be some local cause, and on inquiry found they were living largely on weeds, so I took that to be the cause.

The swelling in all the cases was peculiar in its appearance. The skin seemed swollen to its limit, and in various places it had a dusky hue that precedes gangrene, but in only one case did gangrene occur. This was in a woman who delayed coming for treatment until about eight days after the trouble began. She did not come again for a week, but sent for medicine. On her second visit the swelling had all disappeared, but the skin of the forehead, temples, eyelids, and scalp felt and looked like black leather. Slight pressure on it would make pus ooze out at various places where the skin had broken. The woman eventually made a good recovery.

One of the most interesting features was the quick response to treatment. One day's treatment reduced the swelling of the eyelids so that they could be opened, and in less than a week the worst cases were well except for the ulcers left by the gangrene mentioned above, which took some time to heal. The patients felt that they had been restored to life, and every one came back to show us she had recovered, something remarkable for the Chinese, who are very similar to the ten lepers in the Bible, one only of whom returned to give thanks. The treatment was quite simple—*i.e.*, full doses of chlorate of potassium and a pill composed of extract of gentian, rhubarb, and quinine. I recommended the patients to eat more grain, which I suppose they did, as to most of them money was given for the purpose of purchasing it.

## THE HAND AS AN OBSTETRICAL INSTRUMENT.

By J. HUNTER WELLS, M.D.,
PYENGYANG, KOREA.

During May some twenty-one hundred patients came to the dispensary in Pyengyang, and among this afflicted mass was much of interest and importance. One of the cases was that of a woman, aged twenty years, visited in town. She gave a history of nine lunar months' pregnancy, and of having been in bed for the last ten days and in labor pain. On examination I found the cervix soft, dilated to about the size of a dollar, while slightly protruding was a soft mass which I felt sure was the placenta. I could feel the veins, and I could push it aside. Chloroform was given at once, its further administration being entrusted to an unskilled native assistant who had never seen it given before. After washing the parts hurriedly but thoroughly with a rather strong solution of bichloride of mercury, and washing my hands likewise, I inserted one finger and proceeded to dilate the cervix that way, pushing the placenta aside as I did it. I had only the mercury tablets for solution with me, so I put the forceps in that, disregarding such a small thing as blackening of the instruments. Before trying to use the instruments I pulled the head down as far as possible, applied the forceps, and easily delivered a living and lively female child. I then inserted my hand to get the placenta, but found another baby, which was easily brought down by traction with the fingers under the chin, and as the forceps was at hand it was applied and the second child was delivered. The time occupied altogether was less than twenty minutes, and the point of this article is merely to emphasize the use of the hands as obstetrical forceps. Nearly all the obstetrical cases I have here are of the "surgical interference" kind, and this is the second twin case I have had to do with. In both I feel that I could have properly delivered without forceps and with the woman having no pains to assist the labor. Of course I want the forceps if I can get it, but no physician should sit and wring his hands and let a woman or a baby die because there are no instruments at hand. The human hand is fashioned to perform numerous functions, many of which we know little of as yet.

## SEPTIC INFECTION AND OBSTINATE HICCOUGH DURING THE PUERPERIUM.

By WILLIAM F. BARRY, M.D.,
WOONSOCKET, R. I.

The following case well illustrates the extremely low condition into which a patient may sink, the utter hopelessness of every phase of the case, and yet, withal, recovery may take place.

I was called in consultation to see Mrs. M——, who five days previously had been delivered of her third child. The first and second stages of labor passed without event. The physician in attendance informed me that the uterus then closed in hour-glass contraction, and that, the ordinary methods of expulsion fail-

ing, he introduced his hand into the uterine cavity, and brought the placenta away piecemeal. He told me, and I have every reason to believe his statement, that every precaution was taken to prevent infection. The patient soon had a high temperature, with very rapid pulse and severe chills. In five days the temperature had reached 105° F., and the pulse was 170. At this time I saw the patient. Here was a true picture of septic intoxication: extreme nausea, chills, high fever, rapid pulse and breathing, tympanitic and tender abdomen. The uterus was curetted and irrigated, bringing away a number of small pieces of retained placenta. Though this undoubtedly prevented further infection from this source, the damage had already been done. It was like shooting the dog after the child had been bitten; he surely would bite no more.

The patient was now so weak that every breath seemed to be her last, and a profuse and uncontrollable diarrhœa was added to our woes. But upon the eighth day, with all the above-enumerated symptoms growing rapidly worse, violent hiccoughing set in, and for three days resisted every form of treatment. Upon the third day of hiccoughing the patient was so near death that the family insisted that there was absolutely no use in further treatment; at this time "flowing" started quite profusely, and it was decided to tampon the vagina. Then followed the strangest point in the entire case. A small piece of iodoform gauze was inserted as a preliminary into the os. Simultaneously the hiccoughing stopped; the packing was finished, and the hemorrhage ceased. At the end of twenty-four hours I removed the packing, and strangely enough the hiccoughing returned at once. A fresh tampon was introduced, and again the trouble ceased. This same occurrence took place the following morning, but ceased entirely on the third day. The relief can be explained only on the theory of reflex action, and yet is so singular that I can find no parallel case. The patient was almost comatose at this time, and I commenced copious subcutaneous injections of decinormal saline solution, which gave immediate and lasting benefit. The injections were continued twice daily, and were a very important factor in the woman's recovery.

By this time general peritonitis had developed with dulness localized at and about the umbilicus. Her stomach was in such a condition that rectal alimentation was almost her sole means of sustenance, which together with the daily use of the decinormal saline solution barely kept her alive, with a pulse varying from 160 to 190. The dulness about the umbilicus became circumscribed, and the swelling at this point was great. About the fourth week a surgeon was called in, who said that if a laparotomy could be done some chance might yet be for the patient, but in her present condition it would be fatal. On the following day, with cocaine anæsthesia, I made an incision through the several coats of the abdominal wall and peritoneum, and immediately there flowed out with considerable force large quantities of pus mingled with fæces. The wound was drained with antiseptic gauze, and, strange to say, day by day the patient made an uninterrupted recovery; the fistula in the abdominal wall closed entirely in about two months, and she became strong and well again.

This case teaches one to persevere even in the face of death. It suggested to me that the violent cases of hiccoughing in women may derive lasting benefit from applications or tampons to the os, just as the extreme cases of vomiting of pregnancy do. It also shows the great value of the continued use of saline injections in septic cases.

---

**Aneurism.**—Injections of gelatin have been found efficacious by Lancereaux and confirmed by Stoicesco.

# Society Reports.

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Proceedings of the Twenty-Seventh Annual Meeting, Held at Minneapolis, Minnesota, October 31, and November 1, 2, and 3, 1899.*

*First Day—Tuesday, October 31st—Morning Session.*

The Association met at the First Unitarian Church, and was called to order by the president, Dr. Henry Mitchell, of Newark, N. J., at 10 A.M.

One hundred and ten new members were elected to membership.

**Etiology of Yellow Fever.**—Dr. Henry B. Horlbeck, of Charleston, S. C., chairman, read the report of the committee on the etiology of yellow fever. He referred to a commission which consisted of Drs. E. Wasdin and H. D. Gedding, sent to Havana in 1897–98 by the Marine-Hospital service of the United States to study the cause of yellow fever. Under date of July 10, 1899, this commission reached the following conclusions:

(1) That the micro-organism discovered by Sanarelli, and by him named the bacillus icteroides, was the cause of yellow fever.

(2) That yellow fever was naturally infectious to certain animals; that in some rodents local infection was very quickly followed by blood infection, and that while in dogs and rabbits there was no evidence of this subsequent invasion of the blood, monkeys reacted to the infection the same as man.

(3) That infection took place by way of the respiratory tract, the primary colonization in this tract giving rise to the early manifestations of the disease.

(4) That in many cases of the disease, probably the majority, a primary infection or colonization in the lungs was followed by a secondary infection, or a second colonization, of this organism in the blood of the patient. This secondary infection might be complicated by the co-instantaneous passage of other organisms into the blood, or this complication might arise during the last hours of life.

(5) That there was no evidence to support the theory advanced by Professor Sanarelli, that this disease was primarily a septicæmia, inasmuch as cases did occur in which the bacillus icteroides could not be found in the blood or organs in which it might be deposited therefrom.

(6) That there existed no causal relationship between the bacillus X of Sternberg and this highly infectious disease, and that the bacillus X is frequently found in the intestinal contents of normal animals and of man, as well as in the bronchial secretion.

(7) That, so far as the commission was aware, the bacillus icteroides was never found in any body other than one infected with yellow fever, and that whatever might be the cultural similarities between it and other micro-organisms, it was characterized by a specificity which was distinctive.

(8) That the bacillus icteroides was very susceptable to the influences injurious to bacterial life, and that it was readily controlled by the processes of disinfection, chemical and mechanical, was assured.

(9) That the bacillus icteroides produced in vitro as well as in vita a toxin of the most marked potency, and that from our present knowledge there existed a reasonable possibility of the ultimate production of an antiserum more potent than that of Professor Sanarelli. As there was such a wide divergence of opinion with reference to the bacillus icteroides in its relation to yellow fever, the committee believed the organization of an able and full commission of bacteriologists,

fully equipped and provided with ample means, should be effected, which should be permanently located in one of the yellow-fever-infected cities. Sufficient remuneration should be provided, so that the highest talent in bacteriology might be engaged.

Dr. E. Licéaga, of the City of Mexico, Mexico, presented his eighth annual report of the committee on yellow fever of the cases observed in the Mexican Republic, from the date of his first report, September 12, 1898, to September 15, 1899. He also gave a description of the sanitary stations about to be established in the Mexican Republic to prevent the spread of yellow fever.

Dr. Ismael Prieto, of the City of Mexico, presented data for the bacteriological study of yellow fever.

Dr. Narciso del Rio, of Vera Cruz, Mexico, read a paper in which he pointed out the necessity of making complete and general disinfection of a vessel in order to make it efficacious, and advanced arguments to prove that partial disinfection was useless in cases of yellow fever.

In the discussion, Dr. Thomas J. Turner, of Cold Water, Mich., agreed with the essayist, and stated that disinfection to be useful should be general and thorough so far as cleanliness was concerned. He believed that the germs of yellow fever were carried by articles rather than by persons themselves.

Dr. Antonio Mantienzo, of Tampico, Mexico, followed with a paper in which he advanced considerable evidence to show that yellow fever was a preventable disease.

---

*First Day—Afternoon Session.*

**Laboratories and Public Health.**—Prof. William H. Welch, of Baltimore, addressed the association on the relations of laboratories to public health. He said that laboratories devoted to the study of hygiene were of comparatively recent date, the first being started by von Pettenkofer, of Munich, in 1878. This laboratory contained hygienic, physical, chemical, and biological departments. The problems pertaining to the disposal of sewage, public water supplies, the prevalence of epidemic diseases, and more especially cholera and typhoid fever were dealt with, also the relation of typhoid fever to ground water. The results of the investigations conducted by this laboratory were of inestimable value to the inhabitants of Munich, a city which was once the very hot-bed of typhoid fever, but which was now so free from this disease that von Ziemssen said it was difficult to give practical demonstrations to medical students of the lesions of typhoid. It was about this time that Koch introduced his remarkably simple methods, which rendered possible the isolation of the bacteria of certain infectious diseases. The stimulus of these great discoveries led to the rapid foundation of hygienic laboratories in connection with universities and with boards of health, so that within a few years nearly all the great universities in Germany were provided with hygienic laboratories. Another factor which had exerted a great influence on the development of hygiene had been the occurrence of epidemic diseases, such as cholera, and in this country yellow fever, and possibly it may turn out in the East that the plague may have a similar influence upon public sanitation.

Mrs. Ellen H. Richards, of Boston, spoke of university laboratories in relation to the investigation of public-health problems and to commercial work. For the investigation of questions of great importance and wide bearing, the university laboratory was likely to be the best place just as soon as the university authorities realized its value as a factor in higher civilization. She said that the head of a sanitary laboratory should be a man of absolute probity. His opinions should not be purchasable at any price. He should have unbiassed judgment. He should be well versed in methods of research. He should be patient, quick in action, and well balanced.

**Personal Experience in Disinfection.**—Dr. Wyatt Johnston, of Montreal, narrated the results of his experience during the last three years with formaldehyde as a disinfectant. Steam, sulphur, and other methods of disinfection were tried. He believed there were relatively few conditions under which steam was now necessary for disinfection. Formaldehyde, properly employed, fulfilled all the requirements for municipal and household disinfection. There were, however, certain conditions under which steam seemed indispensable, particularly when considerable penetration was essential; when it was necessary to make rapid disinfection of clothing, bedding, etc., in a hospital, steam was preferable when the articles had to be used immediately afterward. Formaldehyde emitted certain odors afterward which rendered it unsuitable for rapid work. The penetrating qualities of sulphur vapors were deficient, unless the sulphur was used in such a large quantity as to cause serious damage. With formaldehyde he had never done serious damage to the articles that were disinfected by it, and he had no doubt that this was the experience of other observers.

In the discussion which followed, the general consensus of opinion was that formaldehyde was one of the best disinfectants, if not the best one, that had been brought before the profession in the last two or three years.

---

*First Day—Evening Session.*

At this session, addresses of welcome were delivered on behalf of the city of Minneapolis by Honorable James Gray, mayor; on behalf of the State, by Dr. Samuel G. Smith, of the University of Minnesota; on behalf of the local medical profession, by Dr. H. B. Sweetser, president of the Hennepin County Medical Society, and by Cyrus Northrop, LL.D., president of the University of Minnesota.

**Sanitary Progress.**—The president, Dr. Henry Mitchell, of Asbury Park, N. J., then delivered his address. He selected for his subject, "A Review of the Sanitary Progress during the Year." He stated that public interest in all questions relating to the development of a working system for carrying into effect the rapidly unfolding truths of sanitary science had been one of the most prominent features of the period which had elapsed since the association was organized. During this period had occurred nearly all of the substantial improvements in municipal sanitary administration which at present stood engrafted upon our systems of government. He referred in general terms to recent sanitary progress, and spoke more specifically concerning a few of the details relating to the prevention of disease, including sanitary legislation, education of sanitary officers, decrease of infant mortality, vaccination, typhoid fever, tuberculosis, adulteration of foods, and local, state, and national sanitary administration. During the twenty-seven years which had passed since the organization of the association, legislation designed to protect and promote the public health had been obtained in almost all of the States within the territory represented in the membership, and efforts were now being made to secure a greater degree of uniformity in these enactments, and in the methods to be pursued in their enforcement, at least so far as they were related to interstate questions. The hygienic control of milk supplies had assumed a better working basis in numerous localities, and the popular demand for clean milk was beginning to meet with response from a few of the more progressive dairymen. The history of the morbidity in the military

camps of the United States during the recent war with Spain had demonstrated anew the truism that cleanliness of water and food was an indispensable condition to health, and typhoid fever by its prevalence in these camps had further justified its selection as a typical illustration of the value to the public health of a rigid application of the principles of hygiene. The reduction of the death rate in typhoid fever had been chiefly effected by the improved sanitary conditions in towns, and the relations formerly existing between urban and rural districts were now reversed, the proportion of cases of typhoid occuring in scantily populated regions being much larger than in towns. Further study of the methods by which the spread of tuberculosis may be restricted had also engaged much of the attention of local sanitary authorities during the past year, but no general agreement had yet been reached concerning the course to be pursued for the prevention of this disease. Conservative recommendations for checking the prevalence of tuberculosis included the inspection of all bovine animals, meat, dairy products, and dairy premises; the destruction of diseased animals, and the prohibition of the sale of diseased meat and milk; exclusion of diseased persons from markets, dairies, and other premises where food was prepared or sold; frequent and regular disinfection of public conveyances and places of public assembly; disinfection of all infected apartments after death or the removal of patients. Dr. Mitchell then dwelt upon the necessity for establishing in the United States a national department of public health, saying that its importance had been strengthened by recent events, the addition of tropical possessions having added new responsibilities to those already borne by the general government, requiring investigations concerning the distribution and character of preventable diseases occurring throughout the entire territory occupied by the nation.

---

*Second Day—Morning Session.*

**Cause and Prevention of Infectious Diseases.**—Dr. Peter H. Bryce, of Toronto, presented the report of the committee on the cause and prevention of infectious diseases. He said that the past year had been fruitful in experimental work and discoveries in a field which, if not new, was one which had hitherto received but little attention. So early as 1870 Davaine attributed to flies an important part in the spread of anthrax from dead infected materials to living animals, and in the past five years positive experiments had added to the knowledge of the subject. It had been very well established that flies by sucking the blood of diseased persons could transmit disease. Localized epidemics of dysentery had been caused by flies carrying infection from fecal matter. The essayist referred to Simond's paper, which appeared in the *Annales de l'Institut Pasteur*, in which was reviewed the origin of the epidemics of the plague observed since 1898 in China and India, based on personal investigations in Tonkin and later in Bombay. In tracing its spread, abundant evidence was adduced to show that while man may be the occasional agent of the transmission of plague, he was only indirectly so; the author then pointed out the rôle played by rats as the principal source of its propagation. In general he stated that the epidemic of plague was preceded by an epidemic swarming of rats, and he showed from many illustrations that the first persons attacked with plague lived in those quarters where grain was stored up and who were actually employed in granaries and storehouses, as along the quays; and he further illustrated how, through rats in the holds of ships, the disease was carried from port to port. It was pointed out further that the contagion from person to person in hospitals was wholly exceptional, and many physicians in plague hospitals refused to admit the contagiousness of plague.

Dr. Bryce quoted from the marvellous series of reports by Dr. John Simond, the greatest of all sanitarians, who said, in 1874, in the prevention of disease we must "remove the cause of uncleanliness," that was, "remove filth." This eminent sanitarian then illustrated the varieties and degrees of filth as (*a*) putrescent refuse matter, solid and fluid, causing effluvia and pollution by soil soakage; (*b*) overcrowding, thus polluting the two sources of public health, air and water. Dr. Bryce concluded by saying (1) thus we might, as regards typhoid fever, arrange works for disposal of the garbage and sewage of houses, towns, camps, so as to make local accumulations of organic vegetable and animal pollution impossible, in which the typhoid germs might grow, and from which they might be carried to food and drink. (2) By drainage soil pollution by either vegetable or organic matters would be prevented, so that mosquitoes could not breed in the vicinity of habitations and so be in a position to become disseminators of the malarial parasite; and if they were present, houses should be protected against them, especially at night. (3) Houses should be so constructed as to render them not very accessible to rats, and such a condition of cleanliness of rooms, clothing, and persons should be maintained in these that infected matter would not be present, or, if it was introduced, there would not be flies to carry it. (4) As regards ships, the very means which were now in practical operation at well-equipped quarantine stations would amply serve to destroy rats, *i.e.*, sulphur and formol. (5) Passengers should be detained longer than is necessary for the disinfection of a ship and the elapse of the period of incubation of five days for plague, to which, in the presence of actual infection, might be added a protective inoculation.

**Prevention of Contagious Diseases.**—Dr. Frank W. Wright, of New Haven, Conn., read a paper on prevention of contagious diseases. To prevent the spread of contagious diseases, two objects must be accomplished: First, the destruction by disinfection of the poison given out from the sick person, and, second, the prevention of any poison that had escaped disinfection, from coming in contact with susceptible persons—isolation. Certain diseases might be limited by rendering persons immune to inoculation, as in smallpox or diphtheria, it being now practicably impossible for the former of these diseases to obtain a firm foothold in any well-vaccinated community. A good hospital for the accommodation of persons affected with contagious diseases should be maintained in every State. The writer found a short time ago, by inquiry, that of sixty-two principal cities in the United States and Canada, less than one-quarter were provided with decent hospitals for contagious diseases, some not even having a place for the care of smallpox patients. He believed many lives were sacrificed by contagious diseases annually that could be saved if all persons would conscientiously give attention to details and lend support both morally and financially.

Dr. J. E. Monjaras, of San Luis Potosi, Mexico, dwelt upon transmissible diseases in that city, and made some general remarks on their etiology and prevention.

In the discussion, Dr. Charles A. Lindsley, of New Haven, Conn., made the point that the work of enforcing health laws was much facilitated by placing the authority for prosecution directly in the hands of an attorney, rather than leaving it with a doctor, who knew nothing about law. He had found that this plan added much to the effectiveness of work in his State. Reports of infectious and contagious diseases had much improved there of late both in accuracy and promptitude.

Dr. Charles V. Chapin, of Providence, R. I., made an argument for thorough teaching of modern scientific hygiene in universities and medical schools.

Dr. Wyatt Johnston, of Montreal, said that the great trouble was that the time at the disposal of the professors in the schools was so limited as to prevent the introduction of adequate courses. He suggested that diploma courses in hygiene in the universities should be introduced, and advised the appointment of a committee to further his proposition.

Dr. Charles O. Probst, of Columbus, Ohio, related his experience along this line at the University of Ohio, where an attempt was made to hold a hygienic course, but which was defeated by the entire lack of interest upon the part of the class from which the students would be drawn.

Dr. Benjamin Lee, of Philadelphia, advocated the more general teaching of hygiene in colleges and universities.

**School Inspection in Boston.**—Dr. Samuel H. Durgin, of Boston, spoke on the system of school inspection in Boston. The schools were visited daily by physicians who examined any suspicious cases. These physicians were also charged with the duty of seeing that all cases of infectious diseases were properly isolated.

Dr. John N. Hurty, of Indianapolis, said that the jealousy of business men was an important factor in enforcing health laws, and he gave an account of a recent epidemic of smallpox in Valparaiso, Ind., which was reported as chicken-pox by the physicians in that city, supposedly because merchants said it would hurt business. The foolishness of such a course was pointed out. The Indiana State board of health purposed to require a certain standard of knowledge in its health officers.

**The Cause and Prevention of Infant Mortality.**—Dr. Ernest Wende, of Buffalo, presented a report on the cause and prevention of infant mortality. He paid particular attention to the subject of milk industry, which he said should be under both State and municipal control, operating in harmony under similar principles with the identical object in view, both acting together, forming a system of protection from dairy to consumer. The State should exercise its functions and control until the milk passed within the municipal limits and authority, and the control should include every feature and detail of protective sanitation. These features included briefly: (1) The license system, with fee, periodic systematic inspections with revoking power and penalties for dereliction. (2) The inspection system should include inspection of herds (tuberculin tests), food, animal care. (3) Demand for sanitary environment and buildings, correction of existing evils and examination and approval of plans, pending erection of new ones, which should comply with a standard of sanitary construction with special reference to specific requirements of the business—viz., separate milking and stabling quarters, proper cubic air space, non-absorbent material. (4) Scrutiny of water supply, standard feeding, health of employees, hygienic care of utensils and cans, cleanliness and protection in milking. (5) Definite rules governing all procedures, particularly as to the cooling process, preparation for market, and in relation to the varying seasons. (6) The differentiation of the various characters of milk by differently colored or shaped cans, which should be properly labelled with date of milking and time of shipment. (7) Prohibition of milk preservatives and coloring agents, of adulteration, and of the marketing of milk from diseased, sick, or parturient cows, or of the use of disinfectants, their necessity implying bad sanitation. (8) The prohibition, particularly, of refuse or swill food upon any dairy premises, of any food considered unhealthful by reasons of decomposition or fermentation, and of the association of other domesticated or housing animals with cows. (9) A standard of quality, with periodic testing and analysis. (10) Veterinary inspection with destruction and compensation within the State, and quarantine against the introduction of tuberculous cattle from without. (11) This should be as rigid as against pestilence in man, and it was only by this means that the malady could be circumscribed, and its bearing on human life favorably influenced. (12) With this standard of supervision by the State, the municipality should continue the supervision upon the same lines, which might be outlined as follows: (*a*) Continuation of the license system with penalties, together with stringent ordinances covering quality, adulteration, sanitary care, and relation to contagious-disease contamination; (*b*) milk should comply with the State standard as determined by lactometer tests, periodically instituted, as ascertained both in milk houses and on wagons; (*c*) sanitary non-absorbent milk-rooms, of determined size, air space, ventilation, and light; (*d*) specifically constructed, indirectly plumbed cooling and storage boxes, non-communicating with sleeping-rooms, privies, stables, or other influencing rooms; (*e*) wagons properly lettered and numbered, with protection from summer heat; (*f*) stringent prohibition regarding intercourse with houses containing contagious diseases, particularly relating to the exchange of milk bottles and the prohibition of refilling jars *en route;* (*g*) the constant surveillance of contagious disease in relation to milk routes by means of the "tell-tale" register; (*h*) obligatory cleansing of milk utensils by a uniform method, and of cans before returning to the dairy; (*i*) special supervision of and discouragement, if not abolishment, of selling in grocery stores, and milk sellers of similar character, where the business was subordinate to other interests, and there was consequent lack of protective facilities; (*j*) until State and city act in unison in this, where their interests were identical, the adoption of arbitrary interdiction or destruction at the city line of all milk coming from dairies whose conditions, or herds, might have a deleterious influence upon the milk; (*k*) systematic system of reports, with mutual warnings and notification of imperilling conditions.

**Formaldehyde as a Milk Preservative.**—Dr. A. G. Young, of Maine, contributed this paper. He said that the results of his examinations of all the available printed and other reports regarding the action of formaldehyde seemed to justify the following conclusions: (1) That used as a preservative, it tended at least to impair the nutritive value of milk. (2) Its tendency was also to interfere with the digestive processes. In either case it was only a question of dosage, and the limit of safety was difficult to determine. (3) That though the inhalation of formaldehyde gas was much less dangerous than the breathing of the other gaseous agents much used as disinfectants, the results of tests upon animals, and of one case of accidental poisoning of a human being, indicated that formaldehyde taken into the digestive system might produce dangerous and even fatal results. (4) It would be unwise and unsafe to encourage or to suffer the use of formaldehyde in the public milk supply, even under any possible restrictive regulations. (5) In every State, as is now the case in many, there should be a law prohibiting with effective penalties the use in milk of any chemical preservative whatsoever.

---

*Second Day—Afternoon Session.*

**Typhoid Fever.**—Dr. John L. Leal, of Paterson, N. J., described an epidemic of typhoid fever in that

city which was traceable to an infected public water supply.

Dr. H. C. H. Herold, of Newark, N. J., spoke of the great decline in the mortality rate of typhoid fever since the improved water supply of that city.

Dr. Gardner T. Swarts, of Providence, R. I., made a favorable report of a four months' test of a mechanical filter plant at East Providence.

Mr. H. W. Clark, of Boston, dealt with the bacterial purification of sewage.

Dr. Charles V. Chapin, of Providence, presented the report of a committee to examine into the existing sanitary municipal organizations of the country which belonged to the association, with a view to report upon those that are most successful in practical results.

The session closed with a paper by Mr. W. H. Allen, of Philadelphia, on rural sanitation in England.

*(To be Continued.)*

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON OBSTETRICS AND GYNÆCOLOGY.

*Stated Meeting, October 26, 1899.*

Brooks H. Wells, M.D., Chairman.

**Persistent Urachus in an Adult Woman.**—Dr. H. J. Garrigues reported this case. He said that the extra-fœtal part of the allantois carried vessels to the villi of the chorion, and thus eventually served to form an important part of the placenta. The intra-fœtal part became, in time, the bladder, and the other part dwindled into a cord, called the urachus. In this cord was a long cavity subdivided by partitions and lined with epithelium like that of the bladder. Occasionally the cavity communicated with the bladder and formed a urinary fistula. Of fourteen cases described in the literature, twelve had formed in boys. The specimen presented differed in the fact that it was closed at the umbilicus and the bladder extended up to the umbilicus. It had been found in performing a hysterectomy for uterine fibroids on a single woman aged forty-five years. On the tenth day after the operation the patient had died of nephritis, thus giving him an opportunity for further study of the urachus. The bladder extended to the umbilicus, and was situated between the aponeurosis of the abdominal muscles and the transversalis fascia on one side and the peritoneum on the other.

**Pedunculated Fibroma with Twisted Pedicle and Impaction.**—Dr. Paul F. Mundé presented this specimen. The patient, a woman of twenty-seven years, married three months, had been seen by him last July. Three days previously she had been seized with severe pain in the pelvis and a desire to go to stool. Her physician had not been summoned until the following day, when a tender tumor had been found fixed behind the uterus. At that time there had been no fever and only slight nausea. Examination showed the uterus to be immovable and of irregular outline, but the consistence of the mass was rather soft. The pulse was 110 and the temperature 101.5° F. He had concluded that the case was one of ectopic pregnancy with rupture. Forty-eight hours later her pulse had been 120, and the family stated that she had vomited fecal matter. Her general appearance was bad. The woman had been removed to the Mount Sinai Hospital and the abdomen opened. General peritonitis was present, and the intestine was much distended with gas. The tumor arose from the right fundus of the uterus, and was very tightly wedged. The tumor was semi-gangrenous. The intestine was excised, and then gauze packing placed around it. Death had occurred from shock, a few hours later. The speaker said that this was the first case of the kind that he had encountered, but a search through the literature had shown that five cases were on record. In three of these the abdomen had been opened and enterostomy performed; all had proved fatal. In the other two the tumor had been dislodged and recovery had ensued.

**Other Fibroids.**—Dr. Mundé also presented a fibroid that he had delivered through a vaginal incision. It had grown gradually and had produced no symptoms until it had attained the weight of nearly one pound. On account of its size some difficulty had been experienced in delivering it through the incision.

Dr. E. J. Ill, of Newark, exhibited a fibroma illustrating the chronic form of the condition described by the last speaker, except that impaction had not occurred. The patient, a woman of thirty-three years, had been seen by him last November. There was a history of a sudden attack of peritonitis five months previously. Examination had shown what appeared to be a myoma reaching to the navel. When next seen, in September of the present year, she had become so much worse that operation had been demanded and had been performed. Broad adhesions had been found between the tumor and the bladder, and the lower portion of the bowel. It had been found that the tumor with its pedicle had made half a revolution in the abdomen. Three other fibromata, the size of a hen's egg, had been removed. The specimen was interesting because it showed the chronic form of torsion.

Dr. Brooks H. Wells presented a fibroid taken from a fleshy woman, thirty-seven years of age. There had been no symptoms of disease until about three months before, but since that time she had lost so much blood as to make her extremely anæmic. An abdominal hysterectomy had been performed. The main points of interest were the size of the tumor, its peculiar attachment, and the absence of symptoms until such a short time before operation. The tumor was an interstitial fibroid lying in the anterior surface of the uterus. The mass had been absolutely fixed in the pelvis. Both tubes had been occluded and filled with clear fluid. Recovery had been uneventful.

Dr. E. B. Cragin said that the series of specimens just presented fully emphasized that fibroids were not so harmless as many had been taught. This had been impressed upon him in a case seen a year or two ago. The tumor had been watched up to the menopause, and had been growing smaller, but after a while a fibrocyst had formed, which had increased rapidly from hemorrhages into it. The symptoms from pressure had been very serious. In Dr. Mundé's case there had been no special indication for operation at first, and hence the course pursued was entirely justifiable.

Dr. R. L. Dickinson referred to a case in which a fibroid of moderate size had been found attached to the uterus. The patient had been seen by one or two physicians who had advised against operation because of the absence of symptoms. When admitted to hospital there was a six months' pregnancy above the tumor. The rapid growth of the tumor during the pregnancy had locked the tumor in the pelvis, making its removal quite difficult.

Dr. Andrew F. Currier said that the cause in such cases must have been entirely different from that form of torsion which was not very difficult in connection with certain cystic tumors. Where the tumor was so bound down the torsion must have been one of the accidents of growth of the tumor, the growth being such as to interfere with the circulation. He had recently seen a woman, seventy-four years old, who had reached the menopause at the age of thirty years. She had been a circus rider, yet she had had an impacted tumor in the pelvis, which had presented symptoms for only about one month.

Dr. Mundé, in closing, said that he had long held the view that fibroids existing without symptoms did not require removal. The case had led him to feel that in another one of the kind, if the intra-abdominal fibroid had a long slender pedicle he should remove it and so forestall impaction in the pelvis.

**Ovarian Cystoma Complicating Pregnancy.**—Dr. William S. Stone reported this case. A woman of twenty-two, pregnant for the first time, had called on him with reference to her approaching confinement. When seventeen years of age she had had a severe attack of abdominal pain. Her last menstruation had occurred on December 12th. She had been seen by him last July, and at that time the size of the uterus had corresponded to that of one at full term. The fœtal movements were strong. A tumor of regular and smooth outline had been felt behind the cervix, and almost completely filled the pelvis. On July 26th an exploration had been made through a posterior vaginal incision, and the cyst evacuated. The cyst was unilocular, but could not be completely delivered because of the pregnancy. Uterine contractions had set in on the third day after operation, and on the fifth day a small premature child had been delivered by the breech. In the effort at delivery the left thigh of the fœtus had been fractured. The mother had made a good recovery. One week after the birth of the child it had weighed three and a half pounds. It had been kept in an improvised incubator for one month, and fed on modified milk. There were three papillomata on the interior surface of the tumor. The tumor was really a papilloma-cystadenoma of the ovary. A favorable prognosis seemed warranted.

Dr. S. Marx thought it would have been much better to remove the tumor by the abdominal route, under the circumstances, as it would have entailed less traumatism to the uterus. It was this handling of the uterus that seemed to predispose to premature abortion. He had adopted this plan in several cases, and in all of these pregnancy had gone on to full term. A case was cited in which he had been called in at the time of confinement, and had found a large intraligamentous tumor. He had advised abdominal section, but the ignorant husband had refused. He had then rapidly completed labor and delivered the child, but the cyst had ruptured, discharging the fluid into the peritoneal cavity. Even then operation had been refused, but in spite of this the woman had made an uninterrupted recovery. A short time afterward, the cyst having filled up again, she had been operated on at the Presbyterian Hospital and the cyst extirpated.

Dr. Mundé said that if the pedicle was at all long uterine action was not liable to be set up by the removal of the tumor before the period of viability. After viability, if the tumor was small and not growing rapidly, it might be well to wait until delivery had been effected. A month or two after parturition the tumor could be removed. Of course if the tumor had reached an inconvenient size it would not be well to postpone operative interference. It seemed to him a great mistake to operate upon an intraligamentous cyst, whether the woman was pregnant or not, provided it did not extend up very high. During labor the sac could be evacuated, and, in all probability, the child delivered.

Dr. G. W. Jarman said that in the case reported by Dr. Stone the tumor had been thoroughly engaged in the pelvic outlet, and the cervix so high up behind the symphysis that it had been impossible to reach it with the finger. The selection of the vaginal route seemed to him to have been justified. The patient was a frail subject that would not have stood much shock, and hence the proposition had been made to open the cyst from below and evacuate it—not remove it. Finding, however, that the tumor could be brought down so easily, the effort had been made to remove the cyst.

Dr. Cragin said that in an early pregnancy with a small cyst there might reasonably be a difference of opinion regarding the advisability of operating. If it was a small cyst he would probably not operate; if it was large enough to obstruct labor or be pressed and bruised during labor, he would probably operate from above. If, however, the woman had advanced to the eighth month it seemed to him that the problem presented was entirely different. If the cyst was adherent low down in the pelvis and the woman far advanced he would prefer to operate through the vagina, but if too high up in the abdomen it was a debatable question, though most surgeons would probably select the abdominal route. If the larger part of the sac wall was removed and it was then packed with gauze, the chances of recovery without recurrence were good. For this reason he indorsed the course of treatment followed in Dr. Stone's case. The speaker said that he had had three classes of cases of cysts obstructing delivery. One was at the fourth month—a dermoid adherent in the pelvis. He had removed the tumor through the vagina, and at full term the woman had been delivered of a live child. His own feeling was that it was dangerous to leave dermoids in the pelvis and subject them to bruising. As a rule, dermoids when bruised were very apt to slough and give rise to sepsis. In another case, not seen until labor had set in, a cyst had been found bulging into the vagina. He had opened the cyst through the vagina, and had effected delivery without difficulty, and there had been no further trouble. In still another case of cyst with pregnancy he had removed the cyst through the vagina. After its removal he had found, to his surprise, that it was not an ovarian cyst but a cystic kidney. The kidney had, of course, been fixed in the pelvis, and could not have been properly removed except from below. Movable tumors high up were best attacked from above.

Dr. R. L. Dickinson referred to the cyst of Gaertner's duct, running up from the lateral vaginal wall into the broad ligament. He had seen one such case, which had simply required to be drained and packed, and pregnancy had then gone on without further incident.

**Non-Malignant Papilloma of the Vulva.**—Dr. E. J. Ill, of Newark, presented this specimen, which had been taken from a woman aged fifty-eight years, first seen by him two years ago. There had been no vaginal discharge, and no difficulty with urination. For a year previously she had noticed some growth about the vulva. Examination had shown that both the inner surfaces of the vulva were thickened and horn-like in places. The disease had extended from the beginning of the vulva above down to the posterior commissure. The diagnosis of non-malignant papilloma of the vulva had been made. After two years she had returned and demanded removal of the diseased portion. He had, therefore, removed the whole of the vulva, and it was surprising how little loss of contour had been produced. This was the second case of the kind that he had seen. Both the labia on the right side were covered with a horny thickening. The microscope showed this to be a chronic hypertrophy of the papillary layer of the true derma.

**Broken-Down Fibroid—Exstrophy of the Bladder.**—Dr. Philander A. Harris presented a tumor that he had removed, believing it to be a carcinoma that was breaking down. The patient, a woman aged about forty-five years, had been in bad condition and more or less septic. The tumor had been removed from the anterior wall of the uterus. There had been progressive loss of flesh, metrorrhagia, and menorrhagia in spite of two curettings. Microscopical examination

of the growth showed the prominence of fibrous and muscular tissue, and nothing else; it was apparently a broken-down fibroid. Dr. Harris also exhibited photographs of a woman who had been previously subjected to some form of operation. The patient stated that for some time previously there had been no urine coming from the left kidney, and that she knew this because formerly she had been able to force out urine by pressure on that side with her hand. The case was one of exstrophy of the bladder.

Dr. Jarman said that he had had under observation for nine years a case almost the exact counterpart of the one just reported by Dr. Ill. He had operated on her quite extensively, but the disease had recurred. He would like to hear more in regard to the etiology. In his own case there had been a distinct history of syphilis. Each time the excised nodules had been subjected to a competent pathologist, Dr. George C. Freeborn, and the growth had been reported to be a carcinoma.

**The Umbilicus; Its Development and Deformities.**—Dr. A. Ernest Gallant read a paper with this title. He stated that out of forty-eight hundred and thirty-two children seen at the Good Samaritan Dispensary in the service of the late Dr. Van Arsdale, hernia of the cord had been met with in one case at six months, and acquired hernia in two hundred and sixteen. Of these hernia cases one hundred and forty-four had been under one year of age. Deformities of the umbilicus might arise from retrograde changes in the umbilical vesicles and omphalomesenteric duct. There might be incomplete retraction of the abdominal viscera into the abdomen, arrest of development of the abdominal plates, or abnormal attachment of the cord to the umbilical ring. The omphalomesenteric duct might remain patent in any portion of its length. It was a portion of the original umbilical vesicle extending from the skin to the intestine. It might be present as a blind sac—a true Meckel's diverticulum. The duct might remain open, discharging mucus from a sinus of varying depth. When the intestinal end was closed and the end at the skin was open, there would be only a discharge of mucus; when both ends were open the fæces would be discharged at the umbilicus. One author had stated that in the majority of males the urachus was partially open. The part most likely to dilate was that near the bladder, because this was the portion which was the last to lose its function. Ring fistula at the umbilicus was the result of applying a ligature too close to the abdomen. Urachal fistula might arise from some obstruction to the usual and natural channel for the escape of the urine. In one case cited a marked phimosis had been the cause, as proved by the fact that shortly after the performance of circumcision the urachal fistula had closed. The fistula had been satisfactorily closed by the use of a subcutaneous ligature and the subsequent paring and uniting of the edges. A distended urachus not communicating with the bladder might open and discharge from the umbilicus. An extremely rare form of deformity had been described under the name of "amniotic umbilicus." It was characterized by the absence of skin around the umbilicus, its place being taken by the sheath of the cord. The most common variety of urachal deformity was that known as urachal cyst, or the tubulo-cyst of Bland Sutton. Such cysts might remain throughout life without giving rise to any symptoms. They might remain at the vesical end. Last, but not least, was umbilical hernia. This might be either congenital or acquired. In the newly born herniotomy should be performed as soon as possible. Adherent, irreducible, congenital hernia was sometimes met with soon after birth. As soon as the diagnosis had been made laparotomy should be done if taxis failed. The acquired form arose from the giving way of the parts subsequent to the healing of the umbilicus. The tumor was covered with peritoneum and skin. Coughing and straining efforts of other kinds were quite commonly responsible for its development. When mechanical means failed, radical operation was demanded.

**Dressing for Umbilical Hernia.**—The contents of the sac should be reduced, the umbilicus inverted, and then a pad applied. This pad should be made of a flat piece of pasteboard covered with adhesive plaster, and it should be retained in place by plaster strapping. The most important point in the application of this dressing was to bring together the integument over the inverted umbilicus and hold it there by covering the pasteboard pad with plaster, the sticky side of the latter being next the skin. The dressing should be renewed every two or three months.

**Dressing the Umbilicus of the Newly Born.**—Dr. Dickinson said that he had reviewed the entire literature of the last twenty years regarding this subject, or rather the treatment of the cord at the time of birth and for the ensuing few weeks. The treatment of a hernia of the inguinal canal by any operation producing a scar by granulation was now looked upon as bad surgery, and yet since prehistoric times the umbilicus had been treated in this same unsurgical manner. It had not been until 1893 that the suggestion had been made that the hernial opening at the umbilicus should be treated as were other hernial openings. As a matter of fact, though but little known, 3.2 per cent. of all children had infection due to the present method of allowing the cord to slough off. In these cases the sepsis was slight, being only a sapræmia as a rule, but in 5.25 per cent. the sepsis was severe, and in one per cent. proved fatal. This condition of umbilical sepsis was commonly overlooked, a diagnosis of pneumonia, or something of the kind, being made. The hernia commonly occurred at the upper edge. Below was the strong urachus, with its thick covering, and the arteries. A more surgical treatment of the umbilicus would probably banish most of these cases of acquired umbilical hernia. On the inside of the cord was a very strong ring of elastic fibres, as well as of white fibrous tissue, and Morris, the anatomist, was positive that there existed a real sphincter. The existence of a normal apparatus for closure seemed to the speaker almost certain. The only objection to the method of treating acquired hernia advised in the paper was, that the rubber plaster almost always irritated the skin. If the common yellow adhesive plaster were substituted it would answer equally well the purpose for which it was used, and would not cause such irritation.

Dr. C. G. Kerley said that he had used this mechanical treatment for umbilical hernia, and had not observed any trouble from the rubber plaster irritating the skin. The probable reason was that he changed the plaster rather frequently. If the folds of the skin were well brought together there did not seem to him to be any need for a pad of any kind. He had traced many cases of furunculosis and septic dermatitis to a suppurative condition of the umbilicus. In his experience the quickest and best method of healing this suppurative condition of the umbilicus was to fill the opening with a powder consisting of equal parts of starch and subcarbonate of bismuth. It must be renewed every two hours. Mucous polyps of the umbilicus were very commonly met with, and these could be treated very satisfactorily by the application of a ligature, allowing the mass to fall off.

Dr. Gallant closed the discussion. He stated his belief that Dr. Dickinson's surgical dressing of the cord was sound in theory, but he would recommend that Dr. Dickinson should make use of the balsam of Peru and castor-oil dressing as being exceedingly convenient and reliable for this class of cases.

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN ORATION—PATHOLOGICAL SOCIETY; PRESIDENT'S ADDRESS, NEW ARRANGEMENTS—CLINICAL SOCIETY OPENS—OBSTETRICAL SOCIETY—THE RETURN OF MAJOR ROSS FROM THE MALARIAL EXPEDITION—RECENT DEATHS: BISHOP HICKS, M.D., DRS. MOULD, WALLACE, AND BARNES.

LONDON, October 20, 1899.

THE day before yesterday, being St. Luke's Day, the Harveian oration was delivered at the College of Physicians. This was the one hundred and eighty-first oration, and Dr. Poore was the orator. He began, as in duty bound, by commemorating the benefactors of the college during the past year, noticed the condition of medicine in the time of St. Luke, "the beloved physician," and on to the time of Harvey, whose life and work were then briefly reviewed. This brought him to Harvey's direction to "search out the secrets of nature," and in doing so he held that we have made great advances, not only in knowledge but even in manners and morals. Our increased knowledge of the laws of the visible universe he declared "has increased our living faith and added to the glory of God." As there have always been two schools in regard to scientific inquiry, so now there are those who would hinder the search for the secrets of nature. "There have always been," he said, "trustful souls to whom mental progress is painful, who see sin where none is, and who find blasphemy in the simplest acts." He instanced the poor nuns, whose frenzy could not be quieted until the body of Tagliocozzi was removed to unconsecrated ground because he had dared to alter the human form, and the denunciations of anæsthetics barely half a century ago as contrary to Scripture. So now, he said, there are those "who apparently hold that a guinea-pig is of more value than many babies," and that operations on the lower animals, no matter how carefully done, if done for the purposes of research, diagnosis, or relief, and not with the object of making mutton tender, pigs fat, or horses quiet, are to be denounced as atrocities.

The session of the Pathological Society was opened on Tuesday with an address by the new president, Mr. Watson Cheyne, in which he gave a sketch of the history of the society founded fifty-three years ago, at a time when speculation was rife with a view of devoting its attention to the bare facts of morbid anatomy. With the advance of knowledge it became necessary to enlarge the scope of the society, and the rules were modified in 1893. It was now proposed to advance further. To that end the council had decided to make known that the society is open to every kind of pathology, bacteriology, morbid anatomy, experimental pathology, and pathological chemistry. Secondly, to encourage the study of special branches, the subjects will be grouped, each having preference on one evening. Thirdly, four meetings of the session will be held in laboratories. This will give opportunities for criticism and demonstration, and for bringing forward unfinished researches. These four meetings will not be open to the press. Fourthly, authors may, if they wish, publish their papers in *The Journal of Pathology*.

The Clinical Society began work on the 13th instant, the date of my last letter. A rare case of streptococcal meningitis supervening on chronic nephritis was first related by Dr. Rolleston. A man aged twenty-two years was admitted on the eighth day of his illness, with a temperature of 103° F., and rather indefinite symptoms. Next day he had two fits and died in twenty-four hours. At the post-mortem purulent meningitis, due to streptococcal infection, was found and acute nephritis which seemed to have come on in the course of chronic nephritis. No streptococci were visible in sections from the kidney. Unfortunately no cultures were made from the spleen or heart's blood, so it could not be asserted that the infection was confined to the meninges of the brain.

Dr. F. J. Smith said he had not met with such a case in the post-mortem room, and remarked how rarely purulent meningitis followed renal disease, although pericarditis or pleurisy often did.

Dr. Churton, of Leeds, related a case of aneurism of the first part of the arch of the aorta projecting into the right axilla, in a man aged fifty-three years, who was admitted with a painful pulsating swelling on the right side of the chest, half the size of a cocoanut. An aortic regurgitant murmur was heard over the fourth cartilage. The heart's impulse was in the sixth space, one and three-fourths inches external to the left nipple line. The bruit was fine and whiffing, not suggesting large regurgitations. The patient died of internal hemorrhage, and details of the post-mortem were given. The most interesting question suggested by the case was raised by Dr. F. J. Smith, viz., whether the amount of regurgitation could be estimated by a bruit. As the result of his clinical and post-mortem work he concluded that only clinical symptoms afforded any help.

Dr. Chapman quoted Gross to the effect that if the second sound greatly exceeded the first in aortic cases it would indicate extensive regurgitation, but this did not hold good for mitral cases.

Dr. Rolleston thought in aortic cases there was a fair relation between the distinctness of the murmur and the character of the lesions, though he admitted that there were notable exceptions to this. On the other hand, in mitral regurgitation there was but little relation between the loudness of the murmur and the extent of the lesion.

Dr. P. Kidd agreed as to this, but said the amount of regurgitation could be judged by the pulse and the presence or absence of the second sound over the aorta and carotids.

The president, Sir D. Powell, agreed that a bruit gave comparatively little information unless taken in conjunction with valve function.

Dr. F. J. Smith showed a curious case of a girl, aged nineteen years, treated with iron for anæmia in 1895, and improved. Next year, still taking iron, she showed symptoms of peripheral neuritis. In 1898 she had on one hand warts which showed peculiar phenomena of growth and decay. This year she was admitted with grave anæmia, and while in hospital developed nervous symptoms, consisting of (1) prolonged serious interference with respiration, with periods of hours of rapid breathing (sixty-six or more) alternating with hours of very slow breathing; (2) intermittent fits of unconsciousness, with convulsive movements of face, right arm, and leg. No treatment seemed of avail, but she gradually improved, until headache and pain in the legs were the only symptoms. Incisions down to the bone of both tibiæ relieved the latter, but nothing touched the former. The extreme intractability of the case, and the nervous phenomena, apparently central and peripheral, were the chief points insisted on.

Dr. Norman Dalton said until lately he had regarded thrombosis in anæmia as rare, but in December last he found it at a post-mortem extensive in all the sinuses; the patient had died with cerebral symptoms during anæmia. He had since met with some cases of the kind, and one this week which much resembled Dr. Smith's. He said in this, as in so many

other cases of anæmia that did not yield to treatment, inherited syphilis might be suspected.

Dr. Savill recalled a case of a boy, aged fifteen years, who died with extreme anæmia, and at the post-mortem gummata were found.

Dr. Box mentioned another case in which recovery took place under iodide of potassium.

Dr. Rolleston thought that in some points Dr. Smith's remarkable case read like Stokes-Adams' disease.

Dr. Smith, in reply, said, the question of syphilis should be carefully inquired into.

At the Obstetrical Society Dr. Herbert Williamson read a rather elaborate paper on "The Pathology and Symptoms of Hydatidiform Degeneration of the Chorion." Having considered earlier views, he described the development of the chorionic villi and the changes which occurred in them when undergoing myxomatous degeneration. The relation of hydatid moles to deciduoma malignum was considered. The mortality of ten consecutive cases at St. Bartholomew's Hospital had been thirty per cent., and that of twenty-five cases was twenty per cent.

Dr. Herman expressed surprise at the mortality, and thought it had been much less at the London Hospital. In his experience, when the cervix was dilated and ergot given, the mole was usually expelled and the patient got well. He did not remember having to perform any intra-uterine manipulation to remove such a mole.

Several of the fellows referred to the great difficulties of diagnosis, and then Dr. Ludwig Fraenkel, of Breslau, who was a visitor, spoke. He objected to the view, expressed by the society four years ago, that deciduoma malignum was a sarcoma, and said German writers held it certain that the disease arose from the epithelium of the chorionic villi. Hydatidiform mole they regarded as chorio-epithelioma benignum which might become malignum.

The return in good health of the expedition under Major Ross is an event giving great satisfaction not only to the Liverpool School of Tropical Medicine but throughout the profession. I hear that only one member contracted malaria, and he is well again. The experience gained by the expedition promises much. It seems to show that the mosquito is the important link in the chain which had been conjectured; that the genus Anopheles is the chief culprit; that it cannot travel far; that it breeds in small puddles in the vicinity of human habitations, no larvæ having been found in puddles more than forty yards from a native hut; and that such puddles could be easily destroyed.

Among recent deaths that of the Bishop of Bloemfontein may be mentioned, the Rt. Rev. John Wale Hicks, M.D., D.D., etc. He was a graduate in arts and medicine of the London University. Afterward he went to Cambridge and took the tripos in three faculties, medicine, science, and theology. He was then made lecturer in chemistry, on which he wrote a text-book. Afterward he took orders, and eventually was appointed to the bishopric, in which he labored until his death, on the 11th inst. He was not the only medical bishop, those of Rangoon and Likoma both holding the degree of M.D.

Mr. J. T. Mould, F.R.C.S., died on the 10th, in his eighty-second year, after a long and successful career. He took a great interest in all our medical charities, and in the volunteer movement, which he entered at the beginning.

Dr. Alexander Wallace was an M.D. Oxon., and for thirty years physician to the Colchester Hospital. He was a good naturalist, with special knowledge of certain plants and insects. His medical observations were mostly in St. Bartholomew's Hospital reports.

Mr. Wickham Barnes, F.R.C.S., many years secretary of the Poor Law Medical Association, and much esteemed for his work as such, died on the 12th inst.

## "STATE CARE OF THE CONSUMPTIVE."

To the Editor of the Medical Record.

Sir: In the Medical Record of October 28th, containing reports of the discussion on "State Care of the Consumptive," two statements inadvertently attributed to me are inaccurate and misleading. In view of my warm interest in the projects will you kindly allow me to correct two errors? I am made to say (p. 648) that, should the increase in the death rate from consumption continue through the year, "there would be over one thousand deaths from consumption, probably the highest death rate ever known." I stated in substance that the returns to the State board of health for the first eight months of this year showed an increase of six hundred and sixty-nine over the same period for 1898, and that should this rate of increase be preserved through the remaining months of this year there will be an increase of about one thousand deaths, or fourteen thousand for the year. This will be the highest death rate from pulmonary tuberculosis ever known in this State.

Again (p. 648) I am reported as saying: "If the State spent $10,000.000 a year it would be spending only a small fraction of what it should spend—indeed, it was only a question of shifting the expenditure from one place to another." This statement is so extravagant and obscure, that I must disclaim any responsibility for its appearance. I have favored most earnestly the appropriation of $200,000 by the legislature for the purpose of establishing a State sanatorium for incipient consumptives, believing that such action would inaugurate and promote rational relief for these unfortunates, who have too long been neglected. How far the State shall move in this direction the future must decide, but personally strong convictions make me hope that results will justify gradually increasing expenditure and more extensive care of the early consumptive by the State. *I believe in caring for the consumptive at the proper place at the proper time until he is well or improved, not at the wrong place at the wrong time until he is dead.* Many times the question of expense is raised in opposition to State care. My answer has been: If the State should spend the vast sum of $5,000,000 or $10,000,000 annually, *that would represent only a small fraction of the annual loss to the State* by unnecessary deaths, lessened years of labor and earning capacity, cost of caring for the victims while ill, aid for dependents, and cost of degeneracy in offspring.

Those familiar with the introduction of sanatorium treatment in Europe know that many in moderate circumstances have found a boon within their means, and philanthropy and common-sense benevolent associations have assisted the State more and more each year. The adoption of State care will not create a new expense or additional tax. The *expenditure will be shifted from town, city, and county*, where it is now ignorantly employed and largely wasted so far as results are concerned.

Now the consumptive is a unique, pathetic victim of a stupid method of charitable relief. Every other sufferer is provided for in accordance with medical knowledge. He alone has no chance for recovery if poor, and no alternative but to struggle along until he is unable to work or obtain it. We are educating the public, but making it harder for the unlucky by teaching others to fear him often needlessly. After he has had long, abundant opportunity to infect others, beget progeny, and his condition is hopeless, he enters

a hospital if rules have not been passed forbidding it. The Henry law passed by the last legislature gives cities of the first class power to erect and maintain special hospitals for consumptives outside of the city limits. A wise and beneficent step; but will prevention, which is the primary object of the measure, ever be effective to any large degree when isolation or segregation is not compulsory, and circumstances alone will force the late or advanced case to seek admission? Very few have the hardihood to support the radical measure of compulsory isolation, and while the care of advanced cases in special hospitals is most desirable, the benefits to be derived must be slow, partial, and inefficient. The sanatorium treatment of the incipient case will encourage early diagnosis, recovery or improvement, education, ideal isolation before the case becomes a source of danger, and will prevent progeny during the improvement period. The method is scientific, economical, and above all humane, because the sufferer's right to regain health and strength is recognized. It is more like justice than misdirected charity at the wrong end of a problem, and appeals to "the logic of feeling" rather than late sentimental pity. The average costs and the results will pay. To-day money is wasted because the care of the poor consumptive is a series of blunders from beginning to end. Time and a combination of methods are required in the crusade against tuberculosis. They need not conflict. Probably no one act would hurry the adoption of broad, comprehensive measures of prevention—*i.e.*, the germ, the soil, and the influencing condition—so much as State aid.

The physician knows how to attack the scourge of consumption along many lines, but he is powerless. Leaders in charitable work admit that they cannot grapple with the problem of dealing with its victims, and its frightful results. The last appeal is to the State, as there are many reasons why the city or county cannot undertake the work, and whether the State shall act soon or wisely rests with the medical profession as the rightful guardian of the public health.

John H. Pryor, M.D.

Buffalo, N. Y.

## LETTER FROM BEYROUT, SYRIA.

(From our Special Correspondent.)

SUMMERING IN SYRIA—CLIMATE—INSANITARY ACCOMMODATIONS—SMALLPOX.

Syria, October 3, 1899

The summer has come and gone with us. For the last three months all our friends, relations, and foes—all of them that could—have been sojourning on "the mountains."

In temperate spots of the earth everybody goes downward to the sea in his summer; in our subtropical clime all trend upward to the highlands. It is "good-by, winter!" with us; "good-by, summer!" with the others. From our experience we cannot tell of a purer air than we have found on the Syrian hills. The sunlight is intense, sometimes cruel, in its heating in these Eastern lands. This can be guarded against, as any Bedouin will tell you, or concerning which he will instruct you. But there is always here—I speak of our sojourn—sunlight and fresh air. We leave sunlight and fetid air in the lowlands and escape from an atmosphere that, combined with dust and its accompaniments, would breed anything from the genial fungus of sour milk to the frilled "drumstick-headed" microbe of tetanus.

In an hour and a half we go from one climate to another—from a London fog to the Riviera—from the turmoil of New York to the tranquil beauty of the "Thousand Islands." And then our train is so very slow we can pluck flowers and buy grapes as we go along—grapes, and delicious grapes, too, at a half-penny (one cent) a pound. So we reach Aléy, twenty-one kilometres up, by distance, from the seaport. It is not our purport to detail the variations of the scenery in our crawling through and up by our olives, our cedars, and our palm-trees, and—we almost forgot to mention—the sweeping areas of mathematically planted mulberry-trees and the terraces of vines.

We started with "very damp" (our hygrometer is our witness), and got through various stages of dampness. At Aléy (or Aleigh, as some people spell it) it was "damp" and cloudy, with a mist coming up from the valleys every evening and overshadowing the little village with its teeming summer population.

Now let us digress a bit. This village, or town, is not under the control of His Imperial Majesty. Six great nations—no less—look after the interests of "The Lebanon"—properly so called. From an executive point of view, it goes without saying, they do their duty well. You can leave your hat-box open, and nobody will steal your top hat or even your "billy-cock." You may leave some heavy but humble coins of the realm lying on your dressing-room table, and no one will purloin them; if they fall on the floor they will be replaced; if you go so far as to cast anything objectionable on the street or in your neighbor's garden, you will be promptly reprimanded or fined. Your landlord, nevertheless, is permitted to provide you with accommodations consisting at times of an oblong hole, dug out somewhere in his "garden" or his grounds—underground sometimes—in which, or on which, you can neither stand up nor sit down. This "pit" is usually some eighteen inches long by seven inches wide and thirty inches deep. There is no outlet, and the "matter" is removed when there is "no more room." Where "it" is buried we cannot tell; but we have waked up betimes to find the receptaculum—it is not worthy of the word—empty.

The Druses, whose cleanliness is a part and parcel of their religion, are indigenous to the place, and it is practically owned by them. When taxed on the subject of these cess-pits, they complain of the scarcity of water, and of doing as their "fathers" did before them. They don't believe in innovations. They are not so far off, after all, these would-be cleanly Eastern tribes. They don't know what "they know"; and they want to be taught.

The dry-earth system is evidently their standpoint; but they are at a loss as to its relationship with its liability to failure as contrasted with other more advanced methods than their own. For the present we shall leave our friend the Druse to his own devices.

Why these mountain villages should be attacked one at a time by certain zymotic diseases—should be sporadic in their selection—is as puzzling as are the diseases themselves. Water, climate, population, bad hygiene (a very wide term), want of proper precautions (a wider term still), and then—"we cannot tell!" Typhoid had its dole here during the winter of 1895, when it killed some four thousand people in about six weeks. Then came smallpox, beginning at our village of Aléy. Poor Gordon, the American consul here, was the first to bring the news, dying in the hospital in Beyrout. A tomb was erected to his memory the other day, and I cannot close better than by using his words, prophetic as regarded himself. He wrote them, we are told, on his arrival here a year or so before his death, and they seem an inspiration. Here they are, as well as I can recollect them as I saw them on the tombstone over his grave:

"And here he lies
In some lone Syrian town;
While from the alien skies,
With far-off eyes,
The Syrian stars look down."

So he wrote about himself, and so he died; killed by a disease that we all thought was all but extinct at the time. Then came the scourge; but it was anticipated here by the authorities. They cannot keep their streets or houses clean; but they can at least keep their bodies clean, and they can and do insist on vaccination when the enemy appears. And we may add, so far as we have seen, they are successful, these followers of the Prophet, in repelling our filthiest and most easily repulsed disease.

So say not our friends at Leicester in England, it seems — genial but dangerous idiots that they are. They wait for "something to turn up"; but when the "ghost walks" be assured they will be the first to "fly screeching away."

We have had an exceedingly mild summer here—an average of 82° F. in the shade night and day for the last four months. The birth and death rates we cannot give, as no register is kept. Apparently there has been little illness. It has been an exceptionally healthy spring and summer. What the winter season may bring forth we shall let you know later on, with perhaps other details which for lack of time and space must be omitted for the present.

## THE MANURE NUISANCE IN CENTRAL PARK.

To the Editor of the Medical Record

Sir: For your most excellent article on "The Fertilizing of Central Park" you deserve the thanks of every one who walks, rides, or drives there. We who daily enjoy the beauties of Central Park, and who know the similar resorts abroad, will agree there is no place like it so beautiful and so well kept as during seven or eight months of the year, but during the remainder unfortunately we can enjoy it only with mouth open and nose closed. You did not, of course, expect to influence the Park board at once by your clever article—great bodies move very slowly—but you effected more than you probably expected. *The Rider and Driver* has copied and duly credited the whole article, the board of health has taken notice of it, in all riding academies it has been approvingly discussed, and most likely the bicyclists have done the same. Your idea has taken root and shape; it will germinate notwithstanding the Central Park fertilizer.

There is another malodorous object of still greater importance, as it concerns every one of us, and we have to handle it, although it is offensive to the nose, eye, and touch. None is so will suited as yourself with your caustic pen to start a reform and deserve the gratitude of all by protesting against the issuing of dirty greenbacks by the banks. Nowhere in the world would refined people accept such dirty bills as some of the banks give out to their depositors.

Joseph Kucher, M.D.

32 East Sixtieth Street.

**A Plague-Stricken City.**—A correspondent of *The Scotsman* gives a vivid account of the plague at Poona. The scenes to be witnessed in that disease-stricken town almost beggar description. The correspondent referred to says that to De Foe's realistic pictures of the plague in London must be added the Asiatic peculiarities. There is the funeral pyre of the Hindoo for ghastly cremation, deserted the moment it is lit, and then abandoned to the jackals and vultures. There is the ghoulish Mohammedan cemetery, where the bodies are tossed or dragged, and not one foot of earth covers them. So few of the living are left to remove the dead that, as was the case in London, the death cart goes its round and disposes of the victims wholesale.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 4, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 139 | 135 |
| Typhoid fever | 75 | 18 |
| Scarlet fever | 108 | 8 |
| Smallpox | 0 | 1 |
| Measles | 180 | 9 |
| Diphtheria | 224 | 24 |
| Laryngeal diphtheria (croup) | 3 | 5 |
| Cerebro-spinal meningitis | 0 | 6 |
| Chicken-pox | 17 | 0 |

**The Health of Kashmir.**—Dr. E. A. Neve writes in the *Indian Medical Gazette* that during the year 1898 there were twenty-nine hundred and eighteen surgical operations in the Kashmir hospital. Kashmir is, on the whole, wonderfully free from sickness dependent on climate. Great tracts of country lie permanently under water, and many large areas are exposed to annual floods. During the summer months, the valley is little more than an alluvial plain covered with rice-fields and swamps. Mosquitoes abound. And yet, owing to the altitude, malarial disease is quite rare. The Kashmiris hardly suffer from it at all. Diseases of the eye are, however, very numerous, especially ophthalmia and entropion. Cataract is much less common than in the plains. Diseases of the skin, especially those which are parasitic, simply abound. Scabies, for instance, is universal. Digestive affections are extremely common and are often due to the great excess of starch contained in the diet, which consists so largely of rice. Dilated stomach is of frequent occurrence. In the winter, respiratory complaints, especially bronchitis, abound, and rheumatism is very prevalent. There is a fairly representative series of the general diseases observed in Europe, but the variety is more limited, and some affections are conspicuous by their absence, *e.g.*, scarlet fever and diphtheria.

**Dr. Tanner on Diet.**—Dr. Tanner, who some years ago was the hero of a fasting feat prolonged for forty days and nights, is still alive and well at the age of sixty-seven years. The prediction was made by some medical men that his digestive organs would be irretrievably injured by his lengthy abstention from food, and Dr. Tanner prides himself considerably on the fact that despite these gloomy forebodings his health continues good. He is a strict vegetarian, and thinks that a man can live comfortably on the modest sum of twelve and one-half cents per day. Much of the ill health from which many people suffer he puts down to the consumption of pork and badly cooked food. He also wholly disagrees with the manner in which hotel and restaurant managers cater for their patrons, and is of the opinion that the true idea of cooking is to retain the natural flavor of the viands, and not, as seems to be the aim of the modern cuisine, to disguise it.

**Occurrence and Distribution of Influenza.**—Influenza appears usually in an epidemic form, having its origin in some one locality or another, and travelling with great rapidity, often as a true pandemic, over the major part of the inhabited earth's surface. According to Hirsch, the first trustworthy literary records of the disease date from the early part of the twelfth century. Between 1173 and 1874 it made its appearance on eighty-six different occasions. Its first recorded

occurrence in the United States was in Massachusetts in the summer of 1627; since that time it has visited this country with varying degrees of severity twenty-two times. The last pandemic, that of 1889-90, appears to have originated in Central Asia and to have spread thence to Russia, Germany, France, England, and finally to North America. Its occurrence does not seem to be influenced by climate, season, geological or geographical conditions. The ideas regarding the periodicity of its visitations and those relating to the fixity of its spread from east to west receive no support from Hirsch's analysis of the various epidemics. Neither race, nor sex, nor age appears to serve as an important predisposing factor.—A. C. Abbott.

**Scarlatina in India.**—It has been claimed that scarlet fever does not occur among the natives in India. A special interest therefore attaches to an article in the August number of the *Indian Medical Gazette* by Drs. Cook and Caddy, in which it seems to have been demonstrated that the disease does exist independently of outside or foreign infection. Bacteriological experiments tend to confirm this opinion.

**Deal with the Inebriate** as you have successfully dealt with the maniac. Frown not on him as a hardened criminal. Remember he has fallen by the power of a physical agency which has crushed to earth some of the noblest and most gifted. Treat him as a patient laboring under a baffling and inveterate disease and amid many discouragements. Such a measure of success will follow your true curative treatment as will gladden your hearts as men, while it will attest your skill as physicians.—Norman Kerr.

**Origin of the Plague.**—An English weekly journal has the following exquisite theory in regard to the causation of the plague: "Various scientific theorists have suggested what they conceive to have been the origin of the plague in India, but a native official in the western Presidency, who was called upon for a report, evidently thought little of the learned specialists and their ingenious surmises, for his official return was that, having made the most careful inquiries as to how the plague had come into the villages under his charge, he had the honor to state that in his humble opinion the epidemic had arrived incog."

**Parasites in Malaria.**—Investigation has shown that the types of parasite undergo phases which correspond with the cycle of malaria. When a parasite occupies the whole corpuscle an attack of ague is imminent. When the spherules are found a rigor is present. The smaller unpigmented parasites are present during or at the end of the pyrexial stage; the larger pigmented ones being found during the apyrexial interval. In some cases there is a double crop, as it were, of these parasites, which become mature at different hours, and give rise to double quartan, tertian, etc., of this fever.—F. H. Whitsitt.

**The Human Odor.**—The fact that certain animals, and especially the dog, will recognize the propinquity of their masters or friends, although it may have been impossible for them to have seen them or heard their voices, has long since suggested to physiologists and others the idea that every human being has a distinctive odor, peculiar to himself, and which remains more or less constant. Otherwise how would it be possible for the bloodhound, for instance, to take the trail of an individual and follow it for miles through crowded thoroughfares as well as through open country, and unerringly pick out the individual from among hundreds of others? This idea has recently received a signal verification, as we are told by Dr. Bett in the *Archiv der gesammten Physiologie*. The doctor states that a friend of his, with bandaged eyes and every precaution against collusion, was enabled by the sense of smell alone to recognize persons with whom he was acquainted, and to call their names the moment that they came into the room and at the distance of several paces. The experiments were varied in a number of ways, but with the unerring faculty of the bloodhound this man detected the identity of every individual presented. Other instances of a similar keenness are cited by Dr. Bett. According to the man who gave the exhibition, every family has a characteristic odor common to all the members thereof, but the intensity of which usually varies sufficiently among the various members to enable him to distinguish each individual.—*Indian Lancet.*

**Tuberculosis among Natives of India.**—Major W. J. Buchanan writes in the *Journal of Tropical Medicine* as follows: "We now come to a consideration of the prevalence of tuberculous affections in the natives of India. My own experience leads me to believe that tubercle of the lungs is more common in natives than is generally supposed, and that many cases are overlooked in out-patient practice. The patient generally complains only of 'fever.' Emaciation has not the same significance in an Indian hospital as it would have in England. Cough is much less commonly a prominent symptom of phthisis in India. I pointed this out six years ago in an article on tuberculosis in Bengal jails. I have recently come across the following remarks on phthisis in India in an old article in the long-extinct *Indian Annals of Medicine*, by Dr. Hoore, who wrote: 'Phthisis, formerly supposed to be so rare among the natives of India, is now admitted to be a frequent affection, and particularly so among inhabitants of the upper provinces. The disease is frequently somewhat different to what has been observed in England. The extent to which tuberculous disease occurs in colored races has become evident from post-mortem rather than direct diagnosis.'"

**Fresh Air and Women.**—Women, as they grow older, are apt to live much indoors. I believe the fat, flabby, paunchy woman, whether purple or pale, with feeble, irritable heart and "inadequate" kidneys, is usually the victim of rebreathed air. It must, I think, sooner or later be recognized that many of the increasing ills which it has been the fashion to charge on the "hurry and brain fag," incidental to the high state of civilization and the large population, are in reality due to the greater contamination of the air we breathe by the waste products of that population, and that toxins excreted by the lungs will in time take high rank among these as both potent and insidious. If this should come to pass, the present ideas anent ventilation must be abandoned as utterly futile, and the need will be felt, not of letting a little air in, but of letting waste products out.—John Hartley.

**Posture in the Puerperium.**—Dr. W. D. Sutherland, in an article on the puerperium in the tropics, says the three ancient obstetric obiter dicta, "perfect rest," "tight binder," "antiseptic douche," are not by any means the articles of faith they used to be. Discussing as to whether rest in the horizontal position is of benefit, he says: "This is, of course, a great desideratum for the patient; but surely some form of it may be permitted which does not entail her lying absolutely motionless on her back. This is a most irksome position even for one seriously ill, and it favors stagnation and consequently decomposition of the lochia. That the dorsal decubitus does not favor the emptying of the vaginal canal we see every time that we give a vaginal injection. As soon as the woman turns round or gets up, there is a gush of fluid, after all had apparently been drained away. As to this po-

sition being irksome, we need only ask the patient whether she would not like to lie on her side, and hear her eager 'Oh, yes,' to make up our minds on this point."

**No Lepers in Denmark.**—The kingdom of Denmark proper is not known to have any lepers, although it is not impossible that Copenhagen, as all larger cities in Europe, has a few who have contracted the disease abroad. Dr. Ehlers, who is the greatest authority in Denmark, and whose name is known throughout the world for his great work in the interest of the unfortunate lepers, divides the disease into two classes: (1) tubercular and mixed leprosy; and (2) pure anæsthetic leprosy. The latter is not considered contagious, as the bacilli of this disease are not found in any tissues except the nerves. It is therefore the intention to isolate first the patients suffering from tubercular and mixed leprosy.—*Annual Report of the Marine-Hospital Service.*

**A Simple Method of Magnifying Tremors.**—Dr. William P. Spratling, of Sonyea, N. Y., sends the following description of an ingenious method of magnifying tremors: "Fill a plain, round, clear glass bowl, such as a finger-bowl, with perfectly clear water, and place it on a table free from motion or vibration. Insert the finger to be tested into the water near one side of the glass. The motion in the finger imparted to the water will cause concentric waves to flow in rhythmic action to the opposite side of the glass. It is best to make such a test in a dark room, or at night, when a light may be so placed as to pass rays through the water, and which rays will be focussed on the table near the glass. This will magnify the tremors many times. Unless too rapid, they may be easily counted, and if too rapid, a much better idea of the rapidity and intensity of the tremor may be obtained than by simple inspection of the shaking finger."

**Health Reports.**—The following cases of smallpox, yellow fever, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 3, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |
| Arkansas, Batesville | October 26th | 1 | |
| Little Rock | October 26th | 10 | |
| Mananna | October 26th | 1 | |
| Newport | October 26th | 2 | |
| Russellville | October 26th | 1 | |
| Tuckerman | October 26th | 2 | |
| District of Columbia, Washington | October 21st to 28th | 2 | |
| Georgia, Lumpkin | October 22d | Present. | |
| Richland | October 22d | Present. | |
| Illinois, Chicago | October 21st to 28th | 1 | |
| Louisiana, Concordia Parish | October 11th | 1 | |
| New Orleans | October 14th to 28th | 1 | |
| Massachusetts, Chelsea | October 21st to 28th | 2 | 3 |

### TABES DORSALIS—ITS PATHOLOGY, DIAGNOSIS, AND TREATMENT.[1]

BY CHARLES L. DANA, M.D.,

NEW YORK

I DO not understand that I am expected to make any original contribution to the subject of tabes, but rather to present the results of my personal studies and experience. I shall be forgiven, therefore, I trust, if what I say seems to be somewhat lacking in novelty.

**Nature of Disease.**—Tabes is a systemic disease, picking out certain parts of the spinal cord and its roots and certain cranial nerves. It is not a constitutional trouble, but is sharply limited to the nervous system. Its effects, outside of the nervous system, are secondary. It attacks first the posterior spinal roots and their termination in the posterior spinal column. The fibres of these roots arise from the posterior spinal ganglia. One part of these fibres passes into the posterior column and makes up the greater part of it; the other part passes outward and forms the sensory nerves. The spinal ganglionic cell with its central and peripheral processes forms a nerve unit or neuron and is called the peripheral sensory neuron. It is this neuron which is the original and main seat of the disease. It may, in the advanced stage, be entirely destroyed. The fibres or neurons of the spinal ganglia develop at different periods of fœtal life; probably those for touch and temperature first, those for muscle sense, equilibrium, and the reflexes later. The later ones are more sensitive to decay, hence in tabes we see first one part, then another of the root fibres and posterior column picked out and destroyed; and correspondingly we find ataxia, loss of reflexes; later, anæsthesia, visceral troubles, etc., in the patient. The typical process is an "elective" degeneration. The pathological change in tabes is also termed "segmental." It affects serially certain segments of the cord, usually at first the lumbar and lower dorsal; at other times it affects dorsal or cervical segments, or the retinal cells and nerve of the eye, which are analogous to the posterior spinal ganglionic cells or peripheral sensory neurons. In accordance with the segments attacked we have different seats of initial symptoms belonging to the legs, trunk, arms, or brain. Tabes sometimes attacks the peripheral motor neurons, causing ocular palsies and muscular atrophies. The same process attacking the cortical cells of the brain with its psychical (association and central) motor neurons, causes paresis; and the exaltation and delusions of grandeur of the paretic are strictly comparable to the hyperæsthesia and pains of the tabetic.

**Nature of the Process.**—Tabes is not an inflammation or the result of an inflammation. It is a primary atrophy or decay attacking the master tissue itself. It is not due to a syphilitic or any other kind of meningitis compressing the roots. Such views are to me so *a priori* impossible that I cannot patiently present them, although I know that a tremendous amount of time, investigation, and learning has been spent in trying to prove a primary syphilitic meningitis. But a chain is no stronger than its weakest link. There is not always a root meningitis, and if so it would not explain an Argyll-Robertson pupil.

We do not know what the nature of this primary and steady decay is. It is probably an early senility attacking these systems of sensory neurons, and this premature old age is due in part to a congenital or acquired weakness of these parts and in part to a toxin acting upon them.

**Etiology.**—This leads me to the well-worn topic of the etiology of tabes. It is practically agreed, I think, to-day that tabes is generally due to luetic infection. If there was no syphilis there would probably be no tabes (or, I may add, paresis). I admit that this is not entirely proven by statistics, but this conviction comes to all as a result of clinical study. American statistics give about seventy-five per cent. of cases with a luetic history of some kind. However, tabes is not syphilis, either primary or secondary or tertiary, and the disease which causes tabes is not often the lues of the syphilographers. For example, a man came to me suffering from tabes in the second stage. He had contracted a supposed primary lesion ten years before. He was treated by two of the best-known and admittedly skilful specialists for this trouble. He received mercury, iodide, baths; he went to hot springs repeatedly. He never had secondary or tertiary symptoms of any kind, but it was his ambition and almost mania to get his system rid of syphilis. His treatment continued at intervals for four or five years, he meanwhile leading a model life; then he developed tabes.

A man came to see me with tabes in its first stage. Nine years before he had had relations with a woman who he learned had syphilis. He went at once to a leading surgeon of Philadelphia, who found a small abrasion which he said was not a chancre. Dr. X—— refused to treat the patient, but the man called two or three times a week for five months, for he was intensely anxious. He was continually examined, but not the slightest evidence of syphilis was ever found, and Dr. X—— refused to treat him for syphilis. He was often examined later, but never had secondary or tertiary symptoms, though always intelligently on the watch. Eight years later he developed tabes. I believe this man received an infection, but how different the clinical picture from that of syphilis as described! There is a something which gets into the system, runs a course unaffected by mercury and iodide, shows absolutely no detectable symptoms, and ends finally in causing a systemic degeneration of the nervous system. During its progress the patient does not give syphilis to others, and if he marries he may have healthy children. Modern syphilitic literature recognizes latent syphilis with final tertiary symptoms, but the progressive degeneration of nervous centres is not tertiary syphilis and is not influenced by it. This fact is not sufficiently recognized. Modern syphilitic treatment does not in the least affect it, still we call it syphilis. Is there not a by-product or a double infection?

[1] Read at a meeting of the New York Academy of Medicine, October 19, 1899.

There are two other factors, and two only, in the causation of tabes: one is heredity, the other over-use or abuse of the spinal cord.

In my experience a large percentage of tabetics are neuropathic or in some way defective as to their neuro-muscular systems. There is no direct heredity, perhaps no striking family neurosis or psychosis; but there is some congenital weakness or embryonic defect. These people are born with badly developed sensory neurons. Tabes is thus in a sense a teratological defect like its cousin, hereditary ataxia. A person with sound and long-lived posterior ganglionic cells may have syphilis a dozen times, but he will not get tabes. This, it seems to me, is the only way to explain its curious vagaries of development. However, it is possible that in exceptional cases a combination of infection with abuse of an organ may so poison and weaken it that degenerative tendency may be acquired, just as any function may be chronically weakened by over-use. So I find that a number of tabetics have been commercial travellers or salesmen who have been a great deal on their feet, men who have greatly overworked or who have indulged in excessive muscular exercise. Sailors, who walk little, rarely have tabes. The importance of this point has been brought out by Edinger, who experimentally produced lesions in the posterior columns of rats by forcing them, when made anæmic by drugs, to exercise inordinately.

I place little importance upon alcohol as a factor in tabes. Drinking does not cause it, nor does moderate drinking modify the course of the disease. Sexual excess, smoking, traumatism are also factors of small account. The same may be said of exposure to cold and a horde of other supposed causes.

**Diagnosis.**—Tabes, when developing in its usual and classical way, is easily recognized. The cardinal symptoms are lightning pains, loss of knee jerk, Argyll-Robertson pupil, ataxic gait, bladder disturbances, and paræsthesia of the extremities. Of these the pupillary symptom is the most important, and it, with one of the other symptoms, is sufficient for a diagnosis in ninety-five per cent. of the cases. The stiff pupil is practically found only in tabes, paresis, cerebral syphilis, and local troubles. When found with cerebral syphilis it usually means that tabes or paresis will develop later.

Loss of knee jerk with one other symptom is usually sufficient for a probable diagnosis. Every healthy person has a knee jerk, and it is lost only in tabes and after certain infectious diseases like diphtheria, in profound stages of alcoholism, and in neuritis, diabetes, and, of course, in crural palsies.

**Unusual Modes of Onset.**—It is not my purpose, however, to dilate on the subject of recognizing classical tabes. In about ten per cent. of cases the disease has an anomalous beginning. The anomalies are due to the fact that the disease is very slow in onset or attacks some unusual segment of the cord. Some of those types are very puzzling and interesting.

Rectal crises. Tabes may, for example, begin with rectal neuralgias and paræsthesias. The patients suffer excruciatingly, and it is usually and naturally supposed that they have fissures, hemorrhoids, or some other local trouble. Very likely some such trouble is present. I have had patients who have had severe operations done on the rectum by surgeons, and, I will add, sometimes with partial relief. At this stage the patient does not always present any other cardinal symptoms, though I believe a very close examination would show the real trouble, for either the pupillary symptom, the lost knee jerk, the slight ataxia, sexual weakness, or luetic history is present.

Neuralgic crises. A most puzzling type of cases is the neuralgic. I have had a patient who had lightning pains for fifteen years and no other tabetic symptoms, except an early ocular palsy and later a loss of knee jerk; then some ataxia and vesical weakness came on. Another patient was treated for malarial and gouty and rectal neuralgias for four years. When seen by me he had normal pupils, no ataxia, normal reflexes, and absolutely no tabetic symptoms; yet a year later some began to develop. It is indeed not very rare that a diagnosis must be made on the pains alone. There is no other malady that gives such extensive severe and intractable pain without objective symptoms.

Gastric crises. Another mode of onset that may obscure the malady is by gastric crises. I do not wish to exploit myself by citing too much the mistakes of predecessors, but one occasionally reaps the fruit of their experience. A patient under my care was treated for two years for dyspepsia and dilated stomach. He had violent attacks of gastric pain with vomiting, and would be for a week or more unable to retain any but the simplest food. He was washed out, dieted, peptonized, and finally given the morphine habit. He had, when brought to my attention, a distinct band of anæsthesia around the waist, and later he showed Argyll-Robertson pupil, loss of knee jerk, and ataxia. These forms of stomach trouble can usually be recognized by the violence of the pains, the absence of evidence of gastric inflammation, ulcer, tumor, or local irritation, the sudden unaccountable onset, and the presence usually of some cardinal symptom of tabes, if it is looked for carefully. The crises last usually several days and suddenly disappear, the patient feeling at once hungry.

Arthropatic type. Occasionally tabes begins with, or is noticed first in consequence of, a sudden painless swelling of the knee or ankle, or an unaccountably easy fracture of a long bone. Such accidents occurring in syphilitics must be carefully examined; their past history, the evidence of bony involvement, the subluxations, the absence of pain comparable to the lesion, and the obstinacy are the factors that are suspicious.

Optic type. Sometimes tabes begins with a slow progressive atrophy of the optic nerve without preceding neuritis. These patients usually show later a loss of knee jerk and a little ataxia; occasionally a few pains. Otherwise their symptoms are slight, and the eventual blindness seems practically to stop the course of the disease.

Syphilitic type. Not infrequently tabes is complicated with manifestations of secondary syphilis. This is shown by headaches, cranial nerve palsies, cerebral thrombosis or hemorrhage, and meningomyelitis with paraplegia. We must bear in mind when nervous syphilis is found that it may pass into tabes or paresis. I cannot, however, undertake to discuss this very fertile field. Exudative or secondary syphilis I believe to be an entirely different thing from tabes, though rather often associated with it. By proper treatment the syphilis can be relieved; then the patient may go on developing tabes or paresis, or he may get well.

Laryngeal crises. Laryngeal crises may be early symptoms, but they are certainly very rare. In the mild cases the patient has a feeling of tickling and choking in the throat followed by spasmodic coughing like that of whooping-cough. In severer cases there is a feeling of suffocation and dyspnœa, followed by loss of consciousness; the face becomes cyanosed, the patient falls to the ground and may have an epileptic convulsion. The trouble can be surely recognized only by the finding of some stigma of tabes.

**Some Early Symptoms.**—Among the early symptoms of tabes which occasionally assist in diagnosis are the areas of unsuspected anæsthesia upon the trunk or limbs. These areas do not often follow the distribution of the peripheral nerves, except those of the

trunk. They are somewhat variable in character, and tactile anæsthesia is more common than that for pain or temperature. Sensitiveness to cold with lack of sensitiveness to heat is a rather characteristic phenomenon.

The symptom of Biernacki is found in about three-fourths of early cases. This is a lack of pain when compression is made over the ulnar nerve at the elbow. It is not of much value.

Another minor early symptom is a deficient sensitiveness of the popliteal nerves when they are pressed or pounded (Bechterew).

Stress has been laid upon the fact that while the knee jerks are absent the abdominal reflexes are usually exaggerated.

Sometimes an ataxia can be found early by measuring the patient's swaying movements with an ataxiagraph. I have found that in early cases the swaying movements are most irregular and jerky, covering not only a larger space but a wider area in every direction, while those of a normal man range in the main anteroposteriorly. Standing on the toes with the eyes closed is the ultimate test of good muscular sense. Tabetics cannot do it even early in the disease.

**Treatment.**—What may be called the present canonical practice in the treatment of tabes is the following: The patient, if in the first or early second stage of the disease, is placed upon a rigorous anti-syphilitic treatment for six to eight weeks. This is followed by a tonic treatment and a course of thermal baths. The treatment is repeated in a year or less. In the intervals the patient is given small doses of iodide and mercury, and is in general treated medicinally as if he had some arterial sclerosis. He receives also courses of electricity, massage, exercises, cord-stretching, spinal counter-irritation, and various supplementary and symptomatic drugs suc'l as ergot, arsenic, aluminum chloride, iron, and the phosphates, in accordance with the choice or experience of the physician.

Can these measures be improved upon? The efficacy of anti-syphilitic treatment is based not on assured personal experience, but on the general fact or alleged fact that tabes nowadays is less severe and rapid than it used to be, and also on the belief that syphilis is the original cause of the disease. It is probable that this treatment does good in some cases, and rarely does harm. I do not know of any neurologist who is able to affirm that it has in his experience surely modified the course of the degenerative process, but many of us have seen it improve the incidental symptoms due to syphilitic exudation, and we have not had the courage often to refuse the treatment in the purely degenerative cases. But in my opinion it is time to change the canonical practice somewhat, and I practise and advise the following:

In the first and second stages all cases with a distinct history of primary and secondary syphilis, either cutaneous or in the nerve centres, should receive rigorous courses of mercury and iodide. In many such patients the tabetic trouble comes on rather suddenly with rapid development of weakness in the legs, amounting perhaps to paraplegia, or with attacks of hemiplegia, or with severe headache, ocular or other cranial nerve palsies, and neuralgias; in other cases there is simply a good history of primary and secondary syphilis. Such patients are in the minority, but they are not rare, and they should receive the canonical therapeusis.

Mercury should be first given. For this purpose the patient should be kept at home if possible and in bed. The best way to give the mercury is by hypodermic injections of corrosive sublimate in doses of gr. $\frac{1}{20}$ once a day, or twice if the symptoms are urgent. The injections are rather painful and require care. The mercury is dissolved in ℥ xxx. of water, to which gr. $\frac{1}{4}$ of cocaine is added. They should be given for two to four weeks, according as constitutional symptoms appear. The patient takes about gr. xxx. of iodide of potassium daily during this time. After the mercurial course the iodide is rapidly followed, 300 grains a day being given if possible. No advantage is gained by larger doses. This medication is continued for about four weeks, so that the patient is under treatment for six to eight weeks. He should have, during all this time, a warm bath twice a week, and oftener if he desires it. If the hypodermics are not well borne the patient should receive inunctions of about ʒ i. of mercurial ointment for six successive days and a hot bath on the seventh, this being repeated for three or four weeks. Mouth washes should, of course, be used. After this course the patient receives the tonic treatment, and here the best medicinal measures are the tincture of iron and some preparation of phosphorus, preferably dilute phosphoric acid, ℥ xxx. daily, or the glycero-phosphate of lime or soda, gr. xl. daily. Such measures must be kept up for two months. During this tonic treatment the patient should receive twenty-four lukewarm baths (one daily) at 94° to 96° F. for eight to ten minutes, followed sometimes by a cool affusion. Some additional comfort and perhaps benefit come from adding salt, soda, carbonic acid, or pine-needle extract to the baths. Instead of the baths at home, he may be sent to some thermal springs.

During this tonic period counter-irritation to the spine may be made by the cautery, or small blisters, and the former should be applied twice a week if there is much pain.

Patients should be made to rest as much as possible all this time, which altogether covers about three months; going to bed early, sleeping late, lying down in the middle of the day for an hour. Driving is a good exercise, walking a poor one, for them.

The diet should be moderate in quantity and simple in character, but nothing is gained by rigid meat diets or rigid vegetable diets. Fattening foods, malt, cream, and oil are to be recommended, however.

The patient has a hard enough time anyway, and it does no good to deprive him of his tobacco or a moderate amount of alcohol, unless there is some individual peculiarity requiring it. So far as possible, the patient should be allowed to look after his business affairs and to take his share in the enjoyments of life.

This anti-syphilitic and bath treatment should be repeated at least once a year. In the interval the patient is given tonic medication and mechanical treatment of various kinds.

If the patient, as is so often the case, comes to me without any history of secondary or tertiary syphilis and without the slightest sign of nervous syphilis, it is utterly useless to put him through the mercury and iodide treatment. At the most we can say, perhaps it does no harm, though I am not so sure of that.

These purely degenerative cases must be treated at once as though they were getting prematurely old, as is the fact they are *quoad* the spinal sensory neuron. They must be put at once on the two months' rest, tonic, and bath regimen just described. The question is, whether we have any specific measures in addition by which the progressive decay can be more surely stopped or slowed up. Such specific is in a measure constituted by an absolutely regular, quiet, institutional life, such as is found in hospitals, and such as cannot always be easily imitated at home. For this reason the poor man who comes into a hospital is more surely helped than the rich man who has the luxuries and anxieties of a home and a family. Institutional life is approximately a specific, but this cannot often be given in early tabes and often not at all; and there is one method of treatment which is on the whole more successful than any other single one, and it

may be looked upon also as measurably specific. It consists in putting the patient to bed and giving him large doses of strychnine and small doses of morphine by hypodermic injection. The doses should be at first very small and should be very cautiously and slowly increased. For example, twice a day I give at first gr. $\frac{1}{60}$ of strychnine and gr. $\frac{1}{60}$ of morphine. At the end of the week these doses are increased to gr. $\frac{1}{30}$; at the end of three weeks to gr. $\frac{1}{20}$, and at the end of five weeks to gr. $\frac{1}{15}$. This latter dose I sometimes increase to gr. $\frac{1}{10}$, but never more. These doses are then decreased gradually to gr. $\frac{1}{20}$ at the end of the sixth week. Phosphates and iron may be given at the same time.

Strychnine is a useful drug in tabes, but also a dangerous one. I have seen it produce pains and even a kind of general collapse of the patient, as though the motor cells were exhausted. Guarded by rest and small amounts of morphine, however, I have never seen any harm and almost always much benefit. After a course of this kind the patient is placed on the two months' tonic treatment as above outlined and given with it small doses of iodide of potassium, *i.e.*, gr. xx. to xxx. a day. This tonic rest treatment, if it proves satisfactory, must be repeated once or twice a year if possible, as is also the iodide treatment in cases in which this is indicated. Sometimes the two can be alternated. There should always be periods of rest when the patient takes nothing. This application of periodic rest and tonic treatment with intermission must, I insist, be persistently kept up.

I do not know of any drugs that are of much benefit to the disease other than those already mentioned. I have seen no reason to believe that silver, arsenic, aluminum, ergot, barium, or gold are any good. Ergot is useful in vesical weakness, but not as a constitutional remedy. Hot baths are dangerous. The medicinal springs, such as those of Hot Springs of Virginia and Arkansas, and Lamalou and Nauheim, no doubt have some favorable influence, but the same, barring the psychical effects and the rest, can often be got at home. Some patients are distinctly improved by careful courses of electrical treatment, including galvanization of the spine and general faradization of the muscles. I do not expect so much from this as from the other measures, but the personal equation is a curious factor in therapeutics, and some persons enjoy and respond to electrical treatment while others are annoyed and irritated by it. The benefit must, of course, be partly psychical and partly due to effects on metabolism and cutaneous and muscular stimulation. Nerve and cord stretching sometimes helps vesical and sexual weakness and pains, and improves the gait. Nothing more than symptom improvement could be expected. The special method of cord stretching, devised by Tourette and Chipault, I have had no satisfactory experience with.

**Fraenkel's Method.**—The treatment of tabes by means of systematic exercises for training the limbs sometimes produces very satisfactory results. The method was elaborated by Dr. Fraenkel,[1] though in its simpler forms it has been applied for many years. It consists in giving the patient a series of exercises arranged so as to train and re-educate the muscular sense. These exercises are to be taken two or even three or more times a day, and last from a few minutes to half an hour. The patient, for example, is made to rise from a chair slowly and carefully, and then sit down; this is done three times. He is made to walk a line on the floor; to step over obstacles; to place the feet on definite spots on the floor at regular and irregular distances. He is trained to overdo in a sense the cerebral and conscious part of ordinary automatic acts, until these acts become automatically easy.

[1] Münch. med. Woch., No. 52, 1890.

A series of exercises is given in an article published by me in *The Post-Graduate* of June, 1896, and republished in the fourth edition of my "Text-Book of Nervous Diseases."

Fraenkel's method accomplishes more if it is done at first under the direct observation of the physician or a trained masseur. It does not cure or change the course of the disease, and is adapted especially to those cases in the first or second stage which have ceased progressing and in which there is some muscular power. It sometimes causes pains and should be carried out with great care.

For the patient who is in the third stage of tabes and lies bedridden, only symptomatic treatment is indicated. The pains and visceral troubles are to be controlled as much as possible. There are a few cases, however, in which the Fraenkel method of muscular training may be tried. These are patients with whom the disease is practically arrested, who are intelligent and still willing to do something, and who have a fair degree of muscular strength.

Let me say in conclusion a word about the general subject of the therapeusis of tabes. We see every now and then cases which force us to think that this disease begins, runs its course, and ends as though driven on by an inexorable fate. It comes despite all precautions, and progresses, remits, and relapses despite all our therapeutics, we stand helplessly by watching this phenomenon of the rule of absolute law. There are some such cases. They belong to patients with particularly unstable neurons or infected with a particularly malignant virus.

There are other cases in which the patients' vitality is great and the infection mild, the disease stops of its own accord for many years. They do not need treatment. But in the majority of cases the balance between health and disease, between the neuron and the poison is more delicately adjusted, and it swings up or down according as the patient is skilfully managed or not. Hence there is a field for wise and cautious therapeutic endeavor. We cannot do marvels; the disease in most cases steadily though perhaps almost imperceptibly progresses, but we can see it arrested sometimes and relieved often, so that the patient leads a long, useful, and comparatively comfortable life.

**Bibliographical.**—The bibliography of tabes dorsalis is extremely rich, there being over a hundred articles contributed to the subject yearly. A large proportion are devoted to symptomatology. In recent years the questions of pathology and pathogeny have been those to which the more serious work has been devoted.

A very complete review of the pathology of tabes is given by Dr. William G. Spiller (*International Medical Magazine*, June, 1897). A most important original contribution as well as critical review is that by Dr. Emil Redlich ("Die Pathologie der tabischen Hinterstrangerkrankung," June, 1897). A smaller but excellent monograph has been written by Dr. Cl. Philippe ("Contribution à l'étude anatomique et clinique du tabes dorsalis," Paris, 1897).

Most of the therapeutical articles have been devoted to reports upon the exercise treatment. This is well presented in Goldscheider's monograph ("Anleitung zur Uebungs-Behandlung der Ataxie," Leipzig, 1898), and in P. Jacobi's article on the same subject (*Deutsche med. Wochenschrift*, 1898, Nos. 8, 9, and 10).

A paper on tabes by Dr. M. Allen Starr, and a discussion mainly on therapeutics appear in the Transactions of the Association of American Physicians, vol. xiv., 1899. Articles by Patrick (*New York Medical Journal*, February 6, 1897) and Bonar (MEDICAL RECORD, May, 1897) in this country have brought out some interesting facts regarding the anæsthesia of tabes.

# THE PATHOGENESIS OF FUNCTIONAL NERVOUS DISEASES AND THEIR PROPHYLACTIC INDICATION.[1]

By JOHN PUNTON, M.D.,

KANSAS CITY, MO.,

SECRETARY AND PROFESSOR OF NERVOUS DISEASES, UNIVERSITY MEDICAL COLLEGE; EDITOR OF "THE INDEX-LANCET," ETC.

GENTLEMEN: In scientific research the closing days of the nineteenth century present a scene of unusual feverish activity, unsurpassed in any period of the world's history. The demands of the present age are so peculiar and exacting that each branch of science endeavors to outstrip the other in enterprise and novelty. In the chase for something new and novel to create a sensation or attract attenion, the votaries of medicine form no exception, and many a well-established scientific medical fact is ruthlessly thrust aside to give place to some new fad or novel experiment. It is clear to all that much of the work now being done under the guise of medical science is largely in the direction of selfish personal interest, and chiefly pertains to the commercial rather than the truly scientific aspect of medicine. Without any desire to underestimate the labor and value of many worthy members of our profession in their efforts to furnish us with means and measures to combat disease, it is certain that the burden of their desire would far better subserve the needs of the age if it were applied to prophylaxis rather than therapeusis. The adage, "Prevention is greater than cure," is as old as the Decalogue, yet there never was a time when its tenets were more seriously disregarded by the profession, as well as the masses, than the present. Proof of this assertion is unnecessary, for every thoughtful physician recognizes it, yet if there is one truth more than another that is clearly emphasized by the more recent advances in medical knowledge it is the great need of a general practical application of this ancient medical axiom. Honesty compels us to admit that the science of prophylaxis has not kept pace with the needs and demands of the age, and that there is a great lack of interest as well as marked indifference on the part of our profession in promulgating and enforcing its principles. The consequences entailed by such neglect furnish a fruitful source of supply for our theme, and afford abundant material for the pathogenesis of nervous affections. As physicians we recognize that certain causes produce certain effects, and observe on every hand unmistakable evidence of the baleful influence of certain factors, which, when allowed full sway, become of necessity potent noxious agents in the pathogeny of neurotic disorders. Too many physicians conceive that the full function of their mission is simply to minister to disease, while the great and overwhelming importance of its prevention is by them entirely ignored. It is the purpose of this paper, therefore, to call attention to some of the more common elements which experience proves play the most prominent part in the pathogenesis of nervous affections, the pernicious influences of which to some degree, at least, come within the province of the family physician to correct, modify, and even overcome, but which so far have failed to receive the due attention they richly deserve.

All authorities agree that heredity plays the chief rôle in the pathogeny of nervous diseases, consequently its study becomes of the highest importance. As physicians we do not presume to explain all the intricate details concerned in the genesis belonging to heredity, as the laws which govern the transmission of hereditary traits and characteristics are, generally speaking, unknown. But the number and diversity of inheritable deviation of structure and function are endless, and these are recognized and read by all men, and are those with which we as medical men have largely to deal. Such stigmata of inheritance are often the result of imperfect growth, defective nutrition, incorrect habits, injudicious education, and modes of life of the parents, the general effects of which tend to produce histological changes in the blood which morbidly react upon the general development of the nervous system in both parent and offspring. The morbid products resulting from such blood deterioration are readily transmissible, and furnish the germs, or seeds if you please, which establish the neurotic diathesis or nervous constitution. Experience proves that these inherited pathogenic neurotic elements may or may not remain latent for years, but when subject to the evolutionary changes incident to the physiological crises or the stimulating processes of educational, business, social, or professional life, they rapidly mature and strengthen until they manifest themselves in some form of serious nervous disease. The same causes that produce such deterioration in the parent are often allowed to have full sway in the child, already predisposed, and then a still greater neurotic change is liable to occur. That a certain predisposition or tendency to nervous disease is transmitted from parent to child, all are agreed, and in its incipient essence it constitutes that which we term the neurotic diathesis or nervous constitution. This manifests itself by nervous instability and defective innervation of the organic functions materially influencing the normal development of the nervous system of the offspring, and makes itself felt by a constant tendency to degenerative changes in the nerve elements, rendering the subjects of it peculiarly liable to break down under stress of circumstances that would not affect another person inheriting a different constitution. As before remarked, these abnormal conditions of inheritance are largely the result of injudicious and unphysiological modes of life of the parents, which in their essence produce a lesion of nutrition by contaminating the blood, which again produce metabolic changes in its constituents that materially influence and lessen its vitalizing power of the nerve centres. What these special blood changes are, histological, chemical, electrical, toxic, or otherwise, may at present be difficult to explain satisfactorily, but we all understand their effects on the somatic organism, and enough evidence can be produced to warrant the assumption that they underlie and form the basis of the neurotic diathesis. This then becomes one of the mightiest factors in the pathogenesis of nervous affections, and experience warrants the assertion that it is purely a physical defect, a lesion of nutrition, which can be remedied and even cured, and loses half its horror when this is fully realized and understood. This morbid inheritance that underlies the so-called nervous constitution is not therefore a necessarily fatal heirloom (as erroneously supposed), certain at some time or other to overwhelm its victim, but is subject, like all other impoverished blood states, to the laws and principles which govern the science of prophylaxis and therapeusis; and the family physician, in his dealing with the children born of neurotic parentage, cannot well afford to slight the importance of this fact.

The idea that the blood is responsible for much of the prevailing nervous disease is not a new one, nor should it be treated as such, for it has been hinted at all through the ages, but the forcefulness of its practical application by the family physician in its prophylactic aspect was never so apparent as it is the present time. This in large measure is due to improved methods of histological investigation and consequent enlargement of knowledge concerning the blood cell and its constituents. That the integrity of the nervous system depends largely upon its proper blood supply is a

[1] Read before the Mississippi Valley Medical Association at Chicago, Ill., October 5, 1899.

physiological axiom, and any interference with this normal correlation becomes at once a pathogenic factor. When we remember the marvellous blood supply of the nervous system, and how dependent the nerve elements are upon this for their physiological sustenance, we can readily understand the wonderful influence and power the blood exerts in sustaining the integrity of their functional activity. Moreover, we are all prepared to admit how easily the blood absorbs and assimilates all kinds of toxic agents, and the peculiar affinity that certain poisons possess when brought in contact with the delicate nerve tissues; consequently the character of the nutriment supplied to the nerve centres necessarily affects their powers and influence on the somatic organism. All authorities agree that the common neuroses are largely the result of a morbid inheritance, that the actual nervous disease which the physician is consulted for is engrafted upon a predisposing neurotic basis, and that this diathesis furnishes the most favorable soil for their growth and development. Hence the pathogeny of a large majority of functional neurotic affections is in a sense congenital in origin, while a comparatively lesser number are acquired.

We are all prepared to admit that neurasthenia and hysteria constitute two of the most common and widespread of all the functional neuroses, and recent experiments in the pathological laboratory go to prove that in both these disorders there is a rapid disintegration of the red blood corpuscles, resulting in the production of an abnormally large amount of the blood platelets. This causes toxic changes in the blood which have a very baleful influence on the functions of the nervous system. Indeed it matters but little what functional neurosis we analyze, the result in large measure is the same. For instance, in studying the pathogeny of epilepsy, hysteria, chorea, neurasthenia, neuralgia, and other allied affections, we are all compelled to recognize the inherited predisposing tendency that led to their development, and when these pathogenic factors are still further microscopically scrutinized the histological elements of the blood are often found to be the offending agents.

In thus recognizing the blood as the noxious agent in the pathogeny of the various neuroses it cannot be denied that environment, education, occupation, habits, marriage, physiological crises, and general careers in life are powerful adjuvants in favoring and promoting pathological changes in the blood which not only exaggerate the pernicious effects of the morbid inheritance, but react upon the nervous system in such a manner as to produce actual nervous disease. But all such agents are usually secondary to the primary cause, for it must be confessed that even in the acquired neuroses, much less the congenital, such factors spend their force first upon the blood and its circulating medium, which again reacts upon the nervous constitution of the individual. That the blood is the chief pathogenic factor in the production of the various functional neuroses is something more than theory can be firmly supported by a fourfold proof: First, by analysis of the family history; second, by actual demonstration in the histological laboratory; third, by clinical observation and experience; fourth, by actual results in their treatment.

All authorities agree that the vast majority of the functional neuroses are engrafted upon a neurotic constitution, which may be congenital or acquired, and it is known that it can be produced by changes in the blood incident to the causes already referred to. Recent experiments with human blood in the pathological laboratory go to prove that in certain forms of nervous disease the erythrocytes of the blood disintegrate, while the platelets undergo an abnormal multiplication resulting in pathological changes that can easily be demonstrated, and that these morbid products circulating in the blood have a very pernicious influence on the nerve elements, favoring the production of neurotic disorders. Those of us who are brought daily in contact with the various forms of nervous disease cannot fail to be impressed with the large number of neurotics who present undoubted clinical evidence of malnutrition and impoverished blood states which in itself suggests at least the blood as the chief pathogenic factor. Moreover, when the nutrition of such patients undergoes improvement by scientific methods of therapeutics and dieting, the nervous phenomena invariably give evidence of partial if not complete restoration. Even in those cases in which the clinical evidence is not so apparent, remedies that nourish the nerve elements and sustain their functional integrity are rewarded by changes for the better. If, therefore, it can be demonstrated by reference to a large number of family histories that the great majority of the neuroses are based upon an inherited or acquired predisposition or neurotic constitution, and that this again is recognized in the laboratory as a lesion of nutrition or change in the constituents of the blood, which receives further support clinically by the large number of neurotics suffering from malnutrition, and that when these conditions are remedied the nervous phenomena improve and often disappear, it would suggest at least the validity of the argument set forth that the blood is largely the responsible pathogenic factor in the production of the various functional neuroses.

If these premises are tenable, and certainly the trend of modern scientific research favors their validity, then it no longer remains a theory, but becomes an absolute scientific fact, and as such deserves the recognition it richly deserves. Moreover, if it is conceded that the functional neuroses are in their incipiency largely based upon a congenital or acquired neurotic soil that amounts to a lesion of nutrition, which again is subject to pathological exaggeration by the powerful influences of heredity, environment, education, occupation, habits, marriage, physiological crises, and general careers in life, then it would seem that their appropriate prophylactic and therapeutic indications are clearly defined. Family physicians who have the professional guardianship of persons, more especially children, known to possess this neurotic vulnerability should fully recognize the dangers accruing from its neglect, and prescribe for them the inexorable laws of prophylaxis, and therapeutic measures that tend to nourish and sustain the integrity of the nervous system. Pure blood should be the lofty ambition of every individual, and one way to secure this is by wisely regulating marriage, and by the adoption of all civil and legal measures that favor its production. The medical aspect of sociology, as embodied in the clinical study of heredity, environment, education, criminology, intemperance, marriage, and the special relation these bear to the pathogenesis of nervous affections, should certainly claim our most earnest attention. In poverty-stricken districts where the parents are too poor to provide the necessary means to guard against the inevitable results of transmitted taints or other injurious influences referred to, it is our business as physicians to appeal to the State legislature to make the necessary provision for their proper care and protection. That we as a profession are not sufficiently engrossed with the all-important problems of prevention as brought out by our present sociological studies is clear to all, for in the light of facts how can we sanction by our woeful indifference the continued abuse of certain influences which by their very nature tend to generate or develop a serious chronic neurotic invalidism that is wellnigh incurable? The duty of every physician who deals with his profession as a noble and humane science is to

point out the methods of preventing the occurrence of actual disease in latent constitutional defects or other individual vulnerable weakness, rather than to confine his sole attention to the treatment of their more active manifestations. The responsibility of the medical profession in relation to the coming manhood and womanhood of our race is too lightly regarded, and not until we as a unit arise from our indifference and deal positively with the medical sociological problems that confront us in a more practical manner, can we ever hope to stem the ever-increasing tide of neurotic disease, and thus fulfil the true function of our mission as guardians and conservators of public health.

## OPHTHALMIC CONTRIBUTIONS.

By DAVID WEBSTER, M.D.,
NEW YORK.

Case I.—Episcleritis with kerato-iritis. Mrs. M. F. J——, aged forty-one years, was admitted to the Manhattan Eye and Ear Hospital, on May 22, 1888, with episcleritis and kerato-iritis of the left eye. The eye had been inflamed for fourteen weeks, and she had been under the care of a physician all the while. Her pupil was irregularly dilated by the atropine which she had been using; there were diffuse infiltration of the temporal portion of the cornea, general redness of the eyeball, some swelling of the lids, slight catarrhal secretion, and lacrymation, with photophobia. As she had had an attack of rheumatism and admitted that her hair had been falling out, it was at first thought that her eye-trouble might be of syphilitic origin. But further inspection showed a subconjunctival swelling upon the temporal side of the eyeball in juxtaposition with the area of corneal infiltration, and a diagnosis of episcleritis, or sclero-keratitis with iritis, was made. The vision was R. = $\frac{20}{20}$, L. = $\frac{20}{200}$. On May 26th the episcleral swelling was thoroughly cauterized with the platinum cautery, cocaine having been dropped into the eye to prevent pain. Three days later the vision of the affected eye had increased to $\frac{20}{40}$. The diminished swelling was cauterized again on June 2d, and again on June 7th. On June 9th the vision had improved to $\frac{20}{30}$. On the 11th the cautery was applied for the fourth and last time, and the patient was discharged on July 18th, with the eye well and the vision $\frac{20}{20}$. No internal treatment had been used, and locally only atropine and hot or cold applications, in addition to the cautery.

Case II.—Tenotomy of the internal rectus to facilitate the cure of incomplete paralysis of the externus. Melinda L——, aged twenty-five years, came to the Manhattan Eye and Ear Hospital in June, 1887, with incomplete paralysis of the left externus accompanied by an annoying homonymous diplopia. No history of syphilis could be elicited, nor could any definite cause for the trouble be ascertained. She was treated by electricity for about a year without any apparent benefit. On June 8, 1888, she was admitted to a bed in the hospital, and a tenotomy of her left internus was performed. Previous to the tenotomy it took a prism of 27° to fuse the images; the day after the operation the images were fused by a prism of 2°; indeed she could blend the images without any prism, but prism 2°, base out, enabled her to hold them. On June 5th, four days after the operation, her esophoria was 20°. She was discharged on June 6th, and I saw her no more. I may add that both eyes had perfect vision.

Case III.—Congenital cataract of both eyes removed by operation. H. W. G——, aged thirty-seven years, clergyman, consulted me about his eyes on May 31, 1888. He said that he had always been troubled with his eyesight. He had been examined eight years previously by Dr. E. L. Holmes, of Chicago, who told him that he had congenital cataract. He afterward consulted another ophthalmologist in Chicago, who confirmed the diagnosis and undertook to cure the cataracts by internal medication, but failed to make any improvement in his sight. Three weeks before I saw him he consulted Dr. Turnbull, of Philadelphia, who advised needling. Right eye has vision = $\frac{20}{60}$; left eye = $\frac{20}{70}$. The patient could read Jaeger 5 with his right eye, and Jaeger 7 with his left. Notwithstanding his defective vision he had acquired sufficient education to become a moderately successful preacher, but the central blur before his eyes was to him a constant source of annoyance. At his urgent solicitation, therefore, I undertook to try to rid him of his cataracts by such operations as might be indicated. On June 11, 1888, he was admitted to a bed in the Manhattan Eye and Ear Hospital, and under cocaine I needled the left eye, making a small opening in the centre of the anterior capsule of the lens. On June 15th, or four days later, as there was no apparent effect from the first operation, I performed a second and more extensive needling. In fact the lens was almost completely bisected in its horizontal meridian in consequence of a sudden and unexpected movement of the eye at a critical moment. The next day there was considerable reaction; the pupil was contracted, the eye was red, and there was some pain. Instillations of atropine were ordered. On the following day there were no pain and less redness. Atropine was continued thrice daily. June 18th, the third day after the operation, the eye was quite painful, the lens was swollen, and the tension was considerably increased. As it was believed that a long continuance of this increased tension would spoil the sight, it was thought advisable to evacuate as much of the swollen lens matter as possible without delay. Accordingly, with a keratome bent on the flat, an incision was made at the upper sclero-corneal junction, through which most of the lens matter was evacuated by means of pressure and counter-pressure with spoons. The iris receded into its natural position, and the pupil was left circular, and with very little semi-opaque lens matter in it. Iced cloths were applied.

June 19th: There is considerable inflammatory reaction with pain. Two leeches were applied to the temple; iced cloths and atropine were applied locally, and calomel gr. x. was given internally.

June 20th: The inflammatory symptoms continue, and there is now some chemosis. The leeches were repeated, and a hypodermic injection of morphine was given to relieve the pain.

June 21st: All the inflammatory symptoms seem to have increased. A pilocarpine sweat was given, and calomel gr. x. with jalap gr. x. was administered. Iced cloths were kept up day and night, and atropine was dropped into the eye three times a day.

June 23d: The chemosis was greatly reduced. There were no pain, and marked improvement in all respects.

June 26th: Last night the patient had some pain, and was very restless and nervous. The pilocarpine injections were stopped, and the patient was put upon kumyss, as much as he could digest.

July 1st: The patient has had bad nights from pain and nervousness, and had to have a nightly hypodermic of morphine to relieve the pain, and to enable him to procure any rest. He was now put upon mercurial inunctions, half a level teaspoonful of Squibb's oleate of mercury being rubbed into some part of his body or limbs night and morning.

July 5th: The patient is improving daily. The eye is whitening up and the exudation is disappearing from the anterior chamber.

July 7th: The eye is quiet. For some days there has been no pain. The injection is slowly diminishing.

July 10th: The eye is slightly injected; the anterior chamber is clear; the pupil is blocked with exudation. The mercurial inunctions were stopped, and the patient was ordered a generous diet.

July 13th: The patient was discharged with perception of light.

August 4th: Left V. = $\frac{2}{200}$ with + 9 D. The pupil is obstructed by opaque capsule and organized lymph.

September 6th: The patient was again admitted to a bed in the hospital. Atropine was instilled, dilating the pupil irregularly and not widely. The eye was cocainized, and with a knife-needle an opening was made through the membrane. A bandage was applied. At the evening rounds the bandages was removed, and atropine was dropped into the eye.

September 9th: There has been no inflammatory reaction. V. = $\frac{2}{40}$ with the refraction corrected, and the patient reads Jaeger No. 1. Discharged.

September 12th: The patient was readmitted, and a needling was done on the right eye, under cocaine, only a small opening being made in the centre of the anterior capsule.

September 14th: There has been no reaction. Left, V. = $\frac{2}{30}$ with + 10 D. The patient was discharged.

October 7th: The patient returned to the hospital to-day for a second needling of his right eye. A little larger opening was made in the anterior capsule than at the first needling. Atropine and a bandage were applied.

October 13th: There was no reaction. The patient was discharged.

November 19th: A third needling was done on the right eye. In forty-eight hours, as there was no reaction, the patient was discharged.

December 10th: The patient returned to the hospital to-day with a swollen lens, a small portion of which had become detached, and was resting against the posterior surface of the cornea. There is a slight scleral injection, rather sharp pain, and increased tension (+ 1). The pupil responds promptly to atropine and dilates widely and circularly.

December 12th: The patient is detained in the hospital in order to keep this eye under observation during the process of absorption of the swollen lens. He felt no result of the last needling until fifteen days after the operation. Then he felt a sharp, sickening pain in the eye. At the same time a conical swelling of the centre of the lens was observed. This pain soon passed off, and did not return until the 10th instant, when he came to the hospital, and the above condition was noted.

December 14th: Under atropine and cold applications the reaction has passed off. The tension is now normal. Discharged.

December 15th: V. = $\frac{2}{50}$ with + 2.50.

September 13, 1889: The patient was readmitted to the hospital, and a crucial incision was made with a knife-needle in the centre of the anterior capsule of the right lens, and a bandage was applied.

September 24th: From the point in the lens where the crucial incision was made a little white substance passes up to the posterior surface of the cornea.

September 26th: The patient was discharged.

May 7, 1890: The right eye presents a very white lens, and V. = perception of light. The eye having been cocainized, an incision was made with a keratome in the supero-temporal margin of the cornea, and the remaining lens matter, having been broken up with a cystotome, was removed piecemeal by pressure and counter-pressure with spoons.

May 9th: The pupil is filled with cortical substance, but there is no inflammatory reaction. The patient was ordered to have atropine instilled three times a day.

May 18th: The patient was discharged.

May 21st: R. V. = $\frac{2}{50}$ with + 10 D. L. V. = $\frac{2}{20}$ with + 10 D.

June 4th: Right eye, V. = $\frac{2}{20}$ with + 12 D. and 2.50 D. cylinder axis 180°. Left eye, V. = $\frac{2}{15}$ with + 14 D.

July 11th: The patient has constant homonymous diplopia, and has to wear an opaque glass over one eye to get along. The images are brought together by prism 40°, base out. A tenotomy of the right internus was performed, leaving 10° uncorrected. After waiting three hours the images were brought together by prisms 5°, base out, and a part of the time they were fused with his glasses without prisms.

October 28th: With a red glass over the left eye there are vertical images which are fused by prism 20°, base down, over the right eye.

December 29th: Complete tenotomy of right superior rectus with no apparent immediate effect.

December 30th: The patient holds the images together with his glasses. He was discharged.

## THE NECESSITY FOR STATE AID IN PULMONARY TUBERCULOSIS.[1]

By GEORGE W. GOLER, M.D.,

ROCHESTER, N. Y.

For a period of years, as shown by the official reports of the New York State board of health, the number of deaths reported from consumption in New York State has averaged thirteen thousand per year. Upon this basis, assuming the average life of a consumptive to be four years, there are always to be found in the State of New York more than fifty thousand cases of consumption.

During a similar period of years the average number of deaths reported from acute respiratory diseases was over seventeen thousand per year. If to the reported deaths from consumption there are added the number of persons that die of consumption, but whose deaths are reported as due to intercurrent attacks of acute respiratory diseases, the number of deaths and the recorded number of cases of consumption would manifestly be largely increased.

The cost of this enormous amount of preventable illness is considerable. Taking the reported deaths from consumption at thirteen thousand, and assuming that one-half of these persons would have had an earning power of but $200 during life, the sum would amount to $1,300,000. The expense of caring for the sick, at but $200 each, would be $2,600,000. If but one thousand families were left wholly or partly dependent, and the families received an assistance from various charities of but $100 each, the sum would be $100,000.

As consumption is so largely a disease of city life, the cost of consumption to the cities in the State may be approximately computed by referring to the table below, which shows the deaths from consumption and from acute respiratory diseases, together with their percentages of deaths from all causes, for the nineteen largest cities in the State.

For the suppression of consumption the State as yet has given no aid. It has been proven to be both a preventable and a communicable disease. It causes untold misery, much poverty, nearly one-ninth of the reported deaths, and really one-seventh of the deaths from all causes. Its influence upon posterity in its causation of inherited tendency is profound. At

[1] Read at the annual meeting of the New York State Medical Association, October 24, 1899.

the lowest authoritative estimate it is curable in twenty-two per cent. of cases. The State, however, withholds its aid, though the reasons for doing so do not seem clear, if the cost of beginning aid be excepted. For the supression of other diseases more tragic in their course than consumption, the State spends hundreds of thousands of dollars yearly.

* Eleven months.

For the insane and the insane epileptic the State expends about $7,000,000 yearly. Twenty-two thousand insane, of which eight per cent. die annually, and of which at best twelve per cent. are curable, are supported by the State, in its system of State hospitals. For the epileptic population in the State, estimated at thirteen thousand, a beginning has been made at the Craig Colony at an expense for grounds and buildings of $215,000, and an annual expense per capita of $450.

Insanity and epilepsy are tragic diseases attended by the violence of mania and the convulsions of epilepsy, the one violently dangerous to the patient and the public; the other chiefly dangerous to himself and a burden to his relatives. For the one, public safety has demanded a hospital; for the other, public sentiment has demanded an asylum.

The average duration of life of an insane person after admission to a State hospital is about twelve years, and the cost, at the average rate of maintenance of $186 per year, is $2,232. This, including loss of earnings for the period at $150 per year, $1,800; for buildings, furniture, etc., the hospital expense allowed by the State is $550; interest at three per cent. makes a total of $6,231 per capita for the twelve-year period.

For the epileptic, the duration of life in an institution must necessarily be long. At best but six per cent. of the cases of epilepsy are curable.

Consumption, unlike lunacy and epilepsy, is not a tragic disease. Its victims often long possess a semblance of health. A little loss of weight, a little cough, a little fever, a little loss of strength are often all the symptoms that mark the beginning and sometimes even the end of consumption.

Dangerous to himself, as shown by the large death rate, insidiously dangerous to relatives, friends, and to society at large, the consumptive yet pursues his way uncared for, so long as strength and life hold out, finally to retire into a home or public hospital or almshouse to die, usually a slow death, and in dying to endanger the lives of many others. To society, which is more dangerous, the maniac, the epileptic, or the consumptive? The insane of New York State housed in institutions number twenty-two thousand, of which twelve per cent. at best are curable and eight per cent. die annually. The epileptics number approximately thirteen thousand, of which an unknown per cent. die annually. The consumptives number approximately fifty thousand, of which at least twenty-two per cent. are curable and near twenty-five per cent. die annually. The insane are comfortably housed in the State hospitals. Provision is being made for the epileptics. The consumptives have no place provided for them. Even adequate protection against the milk of tuberculous cattle is denied the people of the State. For the insane and epileptic the State expends millions; for the consumptive nothing.

For consumption the loss in health, in life, and in money, as herein given, has been underestimated in every way. The money now spent but furnishes asylums for the dying. It is therefore wasted in so far as any rational results in the prevention or cure of the disease is concerned. Special sanatoria, controlled by the State at comparatively small cost, should be furnished for incipient cases of tuberculosis, where quite seventy per cent. of cure could be realized. Such institutions offer hope for the future in both preventive, curative, and educational work in tuberculosis.

## Progress of Medical Science.

**The Veil as a Cause of Redness of the Nose.**—Rosenbach (*Berliner klinische Wochenschrift*, October 9, 1899, p. 896) calls attention to the development of abnormal redness of the nose in consequence of the wearing of a veil in winter. The discoloration is most pronounced at those points where the veil is most intimately applied to the face. The effect is due partly to the mechanical action of the sharp and rough texture upon a sensitive skin, and to the influence of the watery vapor that collects within its meshes and prevents evaporation. Blood is thus driven from the tip of the nose to adjacent parts, whose blood-vessels in consequence become enlarged and conspicuous. The condition is aggravated if the use of the veil is persisted in on passing from a cold to a warm atmosphere. The alterations tend to become permanent the longer the veil is worn without airing, the longer its injurious action is maintained by compression, the colder the season, and the greater the exposure. Sometimes the cheeks are also affected similarly. The treatment of the condition consists in discarding the veil, avoiding for a time sharp winds and great cold and, when exposure to cold air is unavoidable, sudden changes from a cold to a warmer temperature. Gentle massage should be practised, and applications of a thin layer of lanolin, vaselin, or cold cream may be made, followed by that of some simple powder such as talc or starch. When the use of a veil is necessary, it should not extend below the nasal orifices, so as to permit the escape of watery vapor. Further, it should not be too heavy, nor should it be too tight.

**Osteotomy.**—Dr. De Forrest Willard (*Journal of the American Medical Association*, October 28, 1899, p. 1057) considers osteotomy one of the most simple, safe, and satisfactory of surgical procedures. Its employment is indicated in many cases of ankylosis of joints following rheumatic, inflammatory, or tuberculous conditions, when forcible straightening is impossible. It is also of great service in the treatment of deformities following mal-union from fracture, and of the bending of bones resulting from rickets, congenital deficiencies, etc. If performed aseptically, the injury to the tissues is less than in osteoclasis, and the resultant fracture becomes from the moment of closure of the wound only a simple one. Wedge-shaped oste-

otomy is seldom necessary, even in the presence of exaggerated deformity, as simple section is all that is necessary, the gap resulting from straightening being readily filled in with callus. Plaster of Paris makes the best subsequent fixation splint.

**The Effect of Atmospheric Changes on the Hearing in Cases of Chronic Catarrhal Otitis Media.**—Oppenheimer (*New York Medical Journal*, October 21, 1899, p. 590) concludes that the hearing in at least seventy per cent. of cases with chronic catarrhal deafness becomes worse under adverse weather conditions. The degree of impairment of audition, as influenced by atmospheric changes, is determined to a great extent by the location and character of the pathological process in the tympanic cavity. The morbid alterations most susceptible to barometric variations are those of hyperplasia. In the presence of purely atrophic changes in the middle ear the variations in weather have little or no effect upon the auditory function. Atmospheric influences also impair the hearing by affecting unfavorably catarrhal processes of the upper respiratory tract and Eustachian tube. All things being equal, the impaired audition in cases of chronic catarrhal otitis is diminished more (under unfavorable weather influences) in those whose general health is below par than in those otherwise healthy.

**Advances in Renal Surgery.**—Dr. Edward Deansly (*The Lancet*, October 28th) states that the first step in every operation on the renal organ is to verify or correct the diagnosis. Every operation on the kidney should be so designed as to permit a preliminary exploration. The first problem which concerns us is this: What is the kind and amount of clinical evidence which justifies the surgeon in advising or urging an operative examination of the kidney? We should explore in that case in which persistent morbid condition of the urine is associated with persistent signs referable to one kidney. For example, persistence of even minute quantities of blood and pus in the urine when associated with persistent or frequently recurring painin one loin constitutes a sufficiently good presumption of stone, tubercle, or pyelitis to justify an exploration of the kidney. Clinical investigation should be made to ascertain, first, whether any morbid change of the urine which may be found is or is not of renal origin; and secondly, if renal, whether from one or both kidneys. In many cases the absence of signs of bladder disease, together with well-marked pain, tenderness, and enlargement of one kidney, or typical attacks of unilateral renal colic, is sufficient to constitute not an actual proof, but a strong presumption that the morbid condition of the urine is of renal origin, and it justifies an exploratory operation. Every surgeon must, however, have met with cases in which it has been extremely difficult to decide whether blood or pus in the urine proceeds from the bladder or the kidneys. In such cases hæmaturia may be the only sign discoverable. It is true that there are well-known clinical rules for determining the probable origin of blood in the urine, but of these some are certainly fallacious, and thus are not always applicable. The use of catheterization of the ureters as a means of diagnosis is one which cannot yet be regarded as an indispensable method. The only question is, to what extent the difficulty and danger of the procedure are justified by the value of the information obtained. Dr. Deansly has adopted an original procedure which fulfils the same purpose as catheterization of the ureters, and has many advantages over it. Before operating upon the kidney to which clinical evidence points as the offending organ, he examines the opposite organ through a small abdominal incision not more than one and a half inches long immediately below the ninth rib cartilage. This enables one to obtain, with little difficulty and risk, positive information of great value, such as the presence or absence of stone in the pelvis and upper part of the ureter, or any considerable deformity in the size and consistence of the kidney. These remarks apply to calculus and its accompanying morbid changes. In the treatment of all conditions of the kidney except very large neoplasms the lumbar incision is by far to be preferred to the abdominal incision. Keeping the intestines out of the field of operation lessens the risk of infective peritonitis when the contents of the kidney are aseptic. What is the best position for incising the kidney for the removal of calculus? Experience has shown that wounds of the pelvis heal at least as readily as those of the cortex, and that if there is no obstruction of the urine, there is no fear of the formation of a permanent urinary fistula. As a matter of fact the pelvis and the upper part of the ureters are extremely common positions in which calculi become lodged, and when the kidney has been brought out on the loin it is very easy to cut on to the stone and after extracting it to close the incision with a fine continuous suture. Before doing this the opening in the ureter should be utilized both to introduce a sound into the kidney in order to detect other calculi, and also to pass a fine catheter down into the bladder. Some prefer sutures and some prefer no sutures with drainage. The doctor prefers to close the wound in the ureter completely with a fine continuous suture of silk, and the cortex, when that has been incised, with stouter silk sutures passing deeply through the kidney substance. When the contents of the kidney are healthy, and when obstruction of the ureter can be shown to be absent or can be remedied, there is no reason why the kidney should not be preserved. This applies even to advanced hydronephrosis when the cause of the obstruction can be determined and removed. The presence of infective inflammation and its products in the contents of the kidney greatly limit the scope of conservative measures.

**The Typhoid Fever of Malarial Countries.**—Dr. W. Forbes-Leslie (*The Lancet*, October 28th) believes the intestine to be a tube formed for the passage of certain substances, and fitted throughout with the complicated and highly efficient means of absorption and rejection. Colonies of bacteria here produce septic materials in the form of spores or ferments which, being highly absorbable, pass through the walls of the intestine into the blood-stream, and set up the clinical parallels of the disease which they originate. Now, Nature is above all things preservative, and all her ideas are highly efficient to this end. She must have a means of preventing this invasion of noxious elements, though it seems that the intestines exert a selective power, and act toward all substances as a simple membrane; it is in the liver we must look for this filter, this barrier between the primæ viæ and the vital fluid. Certain eminent authorities believe that the liver has this function. It seems that glycogen has an important function in this respect, for there is an intimate relation between glycogen and the onset of disease, as causes which are most fruitful in diminishing this substance are those which predispose to disease. Thus it may be that the poison gains entrance to the blood, and with it in due course the spores of the disease. But after a time these are rejected and thrown out into the intestine, and become formed bacteria, to develop and disperse other poison till death supervenes. It is probable, also, that most intestinal pathogenic colonies can increase in this way as well as by fission, without further introduction from the original infection, and in face of this intestinal focus of disease, with its continued increase from the blood, one can see how important is the question of intestinal absorption and the

necessity of destroying the constantly renewed foci by sweeping out the primæ viæ by strong remedies. Of these none is better than calomel, for in the early stages, and when judiciously used, it will cut short the disease. Calomel has two virtues—the effect of antisepticizing the tract and promoting the flow of bile, and sweeping out most naturally all offending materials. This treatment should be continued for several days till the blood is free from further infection. Then it remains to heal the ulcer left by the colonies of bacteria, and this will be better insured by a mixture containing chlorate of potash, quinine, and hydrochloric acid; this evolves chlorine gas, which has an antiseptic effect upon the intestines. Plenty of milk and soda water should be given, with stimulants in moderation, and when there are signs of weakness chicken-broth or beef-tea.

**Cerebro-Spinal Meningitis.**—Dr. Henry M. Bracken (*St. Paul Medical Journal*, November) concludes that we should not class all forms of cerebro-spinal meningitis as of a true epidemic type. We should not class cerebro-spinal meningitis occurring as a complication or a sequela of certain epidemic diseases, such as typhoid fever, la grippe, pneumonia, etc., as epidemic. We should be guarded in diagnosticating any given case of cerebro-spinal meningitis as epidemic. The prevention of this error should be avoided by a bacterial examination of the fluid removed by lumbar puncture during life, when possible, or by post-mortem findings.

**Intestinal Antiseptics.**—Dr. Burney Yeo (*Interstate Medical Journal*, October) claims that intestinal antiseptics and evacuants have for a long time been in use without the rationale for their use being known. He considers the subject under four headings: (1) What is the scope of antiseptics? The medical use of antiseptics is different from the surgical use. The surgeon aims rather at asepsis than at antisepsis. In medicine asepsis is impossible. Therefore, we must prevent, or antagonize, auto-infection—*i.e.*, intoxication of the organism with the products of digestion. (2) What is the scientific basis for their use? Certain bacilli are only harmful in the presence of putrefaction or other abnormal conditions. If the bowel becomes abnormal, owing to catarrh, long-continued constipation, or injury, the bacillus coli, which is a normal inhabitant of the bowel, seems to take on a virulent action. When associated with the bacillus typhosus it has the power of intensifying the virulence of the latter. As, then, the virulence of intestinal bacteria depends upon their environment, so by modifying that environment it is reasonable to suppose that we can modify their virulence. (3) Under what conditions are they applicable? Intestinal antiseptics are indicated in gastric catarrh and fermentative dyspepsia; also, dyspepsia, chest pains simulating angina pectoris, vertigo, aphasia, and anuria. Pernicious anæmia has been considered to depend upon some toxin which exerts a hæmolytic action. The use of intestinal antiseptics is rational in cholera, dysentery, and typhoid fever. Typhoid fever often exhibits symptoms of being due to a mixed infection, and this may explain the extraordinary variations in the severity of cases. (4) What are the means of applying intestinal antiseptics? The various intestinal antiseptics are water boiled and cooled, calomel, and salines, both of great value in the early stages of typhoid fever. Salicylate of bismuth and carbolic acid are both useful. Salol is very uncertain. Eucalyptol and thymol are both good, and irrigation of the large bowel in typhoid fever must not be overlooked. The doctor concludes with a warning against the productions of the modern manufacturing chemist who sets up to teach the clinical physician.

**The Association of Hysteria with Organic Disease of the Nervous System.**—Dr. Philip Zenner (*Medical Fortnightly*, November 1st) writes on this subject with the object of calling attention to the association of hysteria with organic disease of the nervous system. Hysteria is looked upon as a disease, not a disgrace. To-day the diagnosis is based upon well-recognized symptoms. The most important factor in the etiology of hysteria is heredity; other causes are alcohol, syphilis, fevers and other debilitating conditions, trauma, shock, and depressing emotions. The same causes may produce organic disease of the nervous system. At the same time organic disease of the nervous system itself not infrequently causes hysteria. In the diagnosis one is aided by noting the personality of the patient, the sex, age, heredity, disposition, and history; also the relations of symptoms to emotional conditions. The most characteristic clinical features of hysteria are the so-called stigmata—anæsthesia, paralysis, contractures, limitations of the visual field, hysterogenic zones, etc. Diagnosis is helped by the peculiar grouping of symptoms. Of great diagnostic import are the globus, and concentric contraction of the field of vision, for hysteria; and hemianopsia, alteration of the deep reflexes, rigid pupils, and the reaction of degeneration, for organic nervous disease. Yet even these symptoms are not pathognomonic, the first mentioned not at all, and hemianopsia, ankle clonus, and rigid pupils have been found in hysteria.

**Blood Examinations.**—Dr. A. L. Benedict's article on blood examinations (*New York Medical Times*, November) is not of particular importance to the hæmatologist, but is to the clinician who wishes to obtain the maximum of practical information at the minimum cost of time. There are four methods in common use for estimating the "richness," that is, the oxygen-carrying power of blood: (1) The enumeration of the red cells, preferably by the Thoma-Zeiss instrument; (2) the quantitative estimation of red cells by the hæmatokrit (centrifuge); (3) the estimation of hæmoglobin by color; (4) the indirect estimation of hæmoglobin by specific gravity, preferably by mixing chloroform and benzol till a density is obtained in which the drop of blood will neither rise nor sink, and then taking this specific gravity by the hydrometer. It will be seen that 1 and 2 estimate cells, 3 and 4 hæmoglobin. The point which one wishes really to determine is the quantity of hæmoglobin, and it is obvious that none of these methods is correct. The writer does not understand why most hæmatologists prefer methods 1 and 2. We wish to transport grain and we inquire as to the capacity of freight cars; which is the more rational statement, that there are so many cars on hand, or that, with no specification in number, there are cars ready whose aggregate capacity is so many bushels? So, regarding the transportation of oxygen by the blood, the writer did not see that it was more scientific to note the approximate number of cells per cubic millimetre than to state the aggregate volume of red cells, which may readily be compared with the normal standard, fifty per cent. The hæmatokrit tells us within five minutes, at slight strain of the muscles of the arm, practically what we may learn from the hæmatocytometer in an hour at the least, with much eye-strain, and necessitating either personal attention or the services of a well-trained, sharp-sighted, and thoroughly conscientious assistant. Some practical hints as to the use of the hæmatokrit the doctor gave as follows: Put the centrifuge on a shelf, so that, if anything breaks, the enormous centrifugal force may be exerted above the head of the operator. Always swing both tubes and average the results. A difference of more than two per cent. in-

dicates imperfect tubes or faulty technique. The blood should be blown from the tubes immediately after reading, to avoid coagulation. To clean the tubes they should be washed first with potassium hydrate solution, then with distilled water, introduced through a funnel connected with the capillary tube by a rubber union. The latter may be "milked" if the fluids do not flow readily. The tubes are dried by blowing air through them by means of a bulb. If the blood does coagulate, a coarse human hair as a stylet should be used. Filter paper or absorbent cotton will prevent the introduction of foreign matter into the tubes during the cleansing process.

**Acute Paralytic Dilatation of the Stomach.**—Brown (*The Lancet*, October 14, 1899, p. 1017) reports the case of a man, fifty-five years old, who it was said was suffering from intestinal obstruction. The patient was in his usual good health up to forty-eight hours before coming under observation, when suddenly he was seized with intense pain in the abdomen, accompanied by incessant vomiting, which continued for forty-five hours, when it ceased. The patient was found to be a well-nourished man in poor condition. The hands were cold, the pulse was small and thready, and the face pinched and sunken. The abdomen was distended above the pubes, but flattened at the sides and in the epigastrium. It was resonant on percussion all over, save between the umbilicus and the pubes, where it was dull, and fluctuation could be felt, and a succussion splash was obtained. The temperature was subnormal. The bowels had been moved slightly earlier in the day, but no urine had been passed for forty-eight hours. The abdomen was not tender on palpation, but the patient was in great pain, turning from side to side constantly, and asking relief from his agony. A catheter was introduced into the bladder, and about a drachm of bloody urine was withdrawn. Rectal examination disclosed a normal condition with some fecal contents. An exploring needle was passed into the fluctuating swelling midway between the umbilicus and the pubes, and withdrew about two drachms of thick, greenish fluid, with a curious smell, recalling the contents of a pancreatic cyst. As the general aspect of the case presented unusual difficulties with regard to a diagnosis, and the only thing that seemed certain was that the man would die shortly if unrelieved, and that this pressure of the fluctuating swelling was the cause of his suffering, it was decided to open the abdomen. Ether was given, and the abdomen was rapidly opened over the most prominent part of the swelling. A tense, thin-walled, rounded cyst was then seen, which contained a dark liquid with some gas. As no colon could be seen or felt, and as the tissues of the cyst-wall seemed to be more like peritoneum than any viscus, it was drawn to the surface, opened, and about three pints of dark-green, viscid fluid closely resembling that of a pancreatic cyst were evacuated. The walls were stitched to the skin, and the wound around was closed. The patient rallied well from the operation, and expressed himself as being much relieved, but he sank five hours later. On post-mortem examination the cyst was found to be a dilated stomach which would easily hold five pints of water. There was no pyloric obstruction. The kidneys showed marked signs of nephritis and were saccular. All of the other organs were healthy.

**The Local Treatment of Puerperal Infection.**—Arnold W. W. Lea (*The Medical Chronicle*, August) states that the conclusions which a study with analysis of forty-eight cases seems to justify are as follows: (1) The rise of temperature over 101.4° F. during the puerperium, not obviously accounted for by other causes, should lead to a thorough examination of the genital passages. (2) If no sufficient explanation is found in the condition of the perineum or vagina, a uterine douche should be at once given with due precautions. (3) If within twenty-four hours the temperature has fallen definitely, no further exploration is required, but the douche may be repeated if the temperature again rises. (4) If at the end of twenty-four hours the temperature is higher, and the pulse rate is increased, the cavity of the uterus should be explored with the sterilized finger. (5) If the initial rise of temperature is great (103° F. or over), with or without rigor, the uterus should be explored at once, not waiting twenty-four hours to observe the effect of the douche. This is more especially indicated if the uterus is bulky, showing delayed involution, since this points to putrefaction of retained products, or to septic endometritis. (6) If clots or placenta are discovered, they should be removed with the finger or the curette, a douche given, and a gauze drain inserted for twenty-four hours. (7) In the great majority of cases it is wiser thoroughly to curette the uterus, with the object of removing the whole of the decidua and retained products. (8) There is no evidence that curettage, if done with every precaution, favors the spread of infection. In a large proportion of cases the infection is rapidly checked. (9) In very virulent infection early curetting with the object of sterilizing the uterine cavity affords the best chances of a successful result. (10) If curettage entirely fails, it must be repeated or not, according to the local conditions present. The prognosis, however, in the absence of a definite localization of the infective process, is bad. (11) In some cases, if curettage fails and there is no evidence of general infection of the blood stream, vaginal hysterectomy, if performed in good time, may be successful. (12) Antistreptococcic serum should be given early and freely in cases of proved streptococcic infection. It is of little use in advanced stages of the disease.

**The Medical Treatment of Movable Kidney.**—In the *University Medical Magazine* for September is an article by Dr. Alfred Stengel, in which are discussed the methods of treating movable kidney by attempting to supply the perirenal fat which has become deficient, and by supporting the organ by an abdominal pad. When emaciation has played a part, forced feeding may succeed and an instance of satisfactory treatment in this way is cited. The writer thinks belts and pads are largely condemned because manufacturers are misdirected. A pad, to be effective, should be so shaped and applied as to make pressure upward, backward, and toward the right, so as to push the kidney toward this normal position. Pads used by the writer have been roughly kidney-shaped, having a concave upper border where the pad is about half an inch thick, and a concave lower border where it may be as much as one and a half inches thick. It should be soft but firm, and covered with leather, the greatest length being about three inches and the greatest width two and a half. Several cases are related.

**The Bacillus of Tuberculosis in Chickens and in Man.**—Since Koch first showed the identity of chicken tuberculosis with that of man, it having been previously confounded with diphtheria, and Ribbert first demonstrated the anatomical differences in the two kinds of tubercle tissue, many bacteriologists, notably Strauss, have attempted to show the variations in the growth characters of these organisms. In the *Centralblatt für Bakteriologie und Parasitenkunde*, 1899, No. 45, vol. xxvi., Matzuschita has given an extended analysis of the results of others, and has been able to grow the organisms on potato, potato with glycerin, alkaline potato, beets, and on gelatin and agar-agar.

He here details at length the morphological characters that separate the two forms, and gives the best *resumé* that is obtainable of late.

**Accidental Vaccination through Mosquito Bites.**—Lueddeckens (*Berliner klinische Wochenschrift*, September 25, 1899, p. 858) reports the case of his own son, one and a half years old, who was vaccinated upon the right arm with glycerinated lymph, which was used also in other cases without ulterior result. On the following day the child was bitten in numerous places by mosquitoes. Although care was taken to prevent the little patient from touching the site of vaccination, he accidentally did so, and in the course of a few days it was observed that the sites of some of the mosquito bites were reddened and swollen. For a time nothing unusual was thought of this, but as pustules developed, it was realized that secondary infection had taken place from the site of primary vaccination. Fever existed for eight days, and the general condition was quite poor. In spite of all care and precaution some of the pustules suppurated and left undesirable cicatrices.

**Can Gonococci be Present in the Absence of Clinical Manifestations of Gonorrhœa?**—It having been contended by Neisser that gonococci may be present in the absence of macroscopic evidence of disease, Schiller (*Berliner klinische Wochenschrift*, October 9, 1899, p. 898) examined bacteriologically the urethra and the cervix in three hundred women coming under observation consecutively for various disorders, without finding gonococci in any instance in which visible signs of disease were not present, scrapings being examined in cases in which secretion could not be detected. In all cases in which gonococci were found pathological secretion also was present. Evidence of catarrhal inflammation may be overlooked unless the urine be retained for two or three hours before the examination, which should be made repeatedly with the aid of the endoscope, and before and after the menstrual period, and irrigation should be avoided.

**The Craving for Stimulants.**—Campbell (*The Lancet*, October 21, 1899, p. 1091) contends that his thesis that the blood normally contains stimulants, that these stimulants exercise a favoring influence on function, and conduce to, and may even be a necessary factor in, the production of the feeling of well-being, explains the widespread liking in man and beast for stimulating substances. This liking, amounting often to a craving, is the expression a great physiological principle. When health is perfect, when the blood is well provided with its proper stimulants and not overcharged with depressants, there is no craving for extraneous stimulants, such as alcohol, tea, or coffee, but when the blood is defective in the one, or surcharged with the other, then is felt the desire for the glass of wine or the cup of tea. In order to obviate this desire the body should be kept at the highest level of health. The more perfect the health the more perfect will be the composition of the blood, in respect to both physiological stimulants and deleterious toxins. A blood properly constituted in these and other respects will exercise a gentle stimulant action on the nervous system, and induce a condition of mild physiological intoxication, which expresses itself in a feeling of well-being and happiness—a condition that cannot be bettered.

**The Treatment of Diphtheria with the Antitoxin.**—Tonkin (*The Lancet*, October 21, 1899, p. 1082) formulates the following conclusions as a result of the treatment of two hundred consecutive cases of diphtheria with the antitoxin: (1) The general mortality is reduced. The mortality for cases treated during the first few days is reduced to about three per cent., and that for all other cases to about twelve per cent. (2) Laryngeal cases treated early are markedly influenced for the better, the death rate being very considerably reduced. (3) The mortality from tracheotomy is very much lessened. (4) There is less need for tracheotomy if treatment is begun early. (5) All ages and both sexes are equally influenced. (6) The chances of nephritis are lessened. (7) When treatment is begun early, albuminuria will not appear, and if it appears it will probably not be severe, and will soon disappear. (8) Paralysis is lessened for cases treated on the first and second days. The mortality from paralysis is not lessened. (9) Extension of the disease to the larynx and parts below was not noted after injection of the antitoxin. (10) The only disadvantage noted after the use of the antitoxin was slight discomfort for a few days from urticarial rashes and pains in the joints in a small percentage of the cases. The conclusions arrived at may be taken as a plea for early diagnosis and early antitoxin treatment.

**The Cause of Death from Industrial Electric Currents.**—Cunningham (*New York Medical Journal*, October 21, 28, 1899) summarizes as follows his views as to the cause of death from industrial electric currents: Industrial electric currents which traverse the whole body transversely or longitudinally in sufficient intensity kill because fibrillar contraction of the heart is produced, and not, as has been hitherto surmised, by inducing total paralysis of that organ or destroying it outright. Such currents neither destroy the central nervous system outright nor paralyze it instantaneously. Death of the nervous system from such currents is due to the total anæmia following a sudden arrest of the circulation. In rare instances, when an electric current traverses only the cerebro-cervical portion of the nervous system in considerable intensity, and for a considerable length of time, it may kill by asphyxia, consequent upon a more or less complete inhibition of the respiratory movements which occurs chiefly during the passage of the current. No existing facts warrant the conclusion that the medullary respiratory centre is paralyzed or destroyed under such conditions. Industrial currents are practically non-lethal to frogs and turtles, as the condition of fibrillation disappears from their hearts quickly and spontaneously after the current has ceased to pass. Such animals can, of course, be killed by the prolonged application of a current of moderate intensity, or by one of enormous voltage and large intensity. Strong electric currents, applied to the surface of the skin, affect the heart in the same manner as currents of less strength do when they are applied directly to the exposed heart. It may be possible for an electric current of enormous intensity and electro-motor force to produce instantaneous death either by its disruptive action, or by causing instantaneous heat coagulation of the cellular constituents of the body. Industrial currents do not kill instantly, although as a result of their action death occurs rapidly. The experiences of individuals who have recovered from severe electric shock indicate that such a mode of death is not a painful one. Spontaneous recovery of the dog's heart from fibrillation induced by strong currents is rare. Such recovery and restoration of the arrested circulation after the external application of a strong current for two or three seconds appear not to take place. Artificial recovery of the excised dog's heart from fibrillation induced by the external application of a strong electric current is possible. Such recovery, with restoration of the circulation and recovery of the nervous system, can be brought about by transfusion of defibrinated blood and venesection.

## THE CLIMATE OF SOUTH AFRICA.

THE climate of South Africa is freely acknowledged to be one of the healthiest in the world. The saying that in war pestilence and disease are far more to be dreaded and claim an infinitely larger proportion of victims than weapons of destruction, has been made and proved so many times as to have become a somewhat wearisome truism. The fight between the British and the Boers has been up to the present marked by terrible loss of life, and will before the end comes result in still further slaughter, but in all probability disease will not add its customary quota of human sacrifice. This prediction is based upon the well-known salubrity of the South African climate, which is perhaps as inimical to the germs of disease as any upon earth. The testimony with regard to the healthfulness of South Africa is unanimous. Its configuration is peculiar and strongly resembles a series of steps. The coast plateau is six hundred feet above sea level; the Southern Karoo is twelve hundred feet, the Central Karoo twenty-five hundred feet, and the Northern Karoo four thousand feet and upward. The least healthy portion of this region to Europeans is that bordering on the coast. *The Lancet*, in a leading article some few years ago, gave an interesting description of the climate of South Africa, which, in view of the events now in progress there, it may not be out of place to quote. "In Cape Colony rain falls chiefly in the winter months, the three hottest months, January, February, and March, being almost rainless at Cape Town. On the east coast, however, at Durban for example, most rain falls in summer, and this is also the rule in the interior, where the winters are usually dry and clear with slight frost in some localities. The Southern Karoo presents a decided contrast to the coast plateau. The climate here is, on the whole, dry, with considerable oscillations of temperature and a greater contrast of seasons. The hottest month is January, with a mean maximum of 87° F., and the coolest is July, with a mean minimum of 36° F. The winters are bright and clear with cold nights, and snow lies for a time upon the mountains. The Northern Karoo, of which the elevation varies from twenty-eight hundred to six thousand feet, stretches to the Orange River and has an extremely dry climate, the rainfall in some parts being as low as two inches, and the general average being about ten inches. On the whole, the winter climate is very agreeable; clear, sunny, bracing days with just a touch of frost in the air being very frequent.

"The Transvaal is an elevated plateau with a very healthy climate. Pretoria is at an elevation of forty-five hundred feet above sea level, and Johannesberg of five thousand feet above sea level. In spite of this elevation the summer heat in these places is very great, and dust storms are frequent. Malaria is common in some parts of the Transvaal during the hot rainy season; nevertheless, the climate in general must be pronounced healthy and favorable to Europeans." The climate of South Africa as a whole may be summed up in these words: "Though the mean temperature of the South African climate is higher than that of the greater portion of Europe, owing to the complete absence of very cold weather, the thermometer, at least in the cooler parts of the country, does not exhibit a higher rise than often occurs in northern Europe."

The deductions to be drawn from the foregoing descriptions are that South Africa is comparatively free from deadly diseases, and this is indeed the truth. It is said to be one of the few portions of the globe that have never been visited by yellow fever or cholera, and many of the other pests of the western world are unknown in this favored land. Low fevers occasionally prevail, and there are also periodical epidemics of smallpox and measles along the coast line, invariably imported by calling ships. Ophthalmia and rheumatic complaints in some portions of the country are more or less common, but may be avoided to a great extent with ordinary care. Of course in the case of an army operating in the field there are certain maladies which are difficult and in some instances impossible to escape, such as enteric fever, diarrhœa, and dysentery. To make a comparison with the dangers from disease threatening the British army in South Africa and those with which our forces in Cuba had to fight, it is indisputable that the lot of the British soldier is in this respect greatly better than was the American. If the campaign against the Boers, however, is a long one, it would be idle to prophesy that disease may not yet play havoc among the British ranks, but provided that the sanitary arrangements are carried out effectively, it would appear that disease will not bulk very largely in the death rate of the invading army.

## THE FEEDING AND TRANSPORT SYSTEM OF THE BRITISH ARMY IN SOUTH AFRICA.

IT is said of the Duke of Wellington that, although of course a consummate strategist, a great deal of his success as a leader must be attributed to his untiring care for the bodily welfare of his troops. He paid at least as much attention to the commissariat department as to his plan of campaign, recognizing that unless the men under his command were, so to speak, in good condition, their ability as a fighting machine was very considerably lessened. Other commanders of mark have given testimony that soldiers to fight energetically and with vim must be well fed, suitably clad, and judi-

ciously and comfortably shod. Therefore on the shoulders of those who are responsible for these vital details rests an awful responsibility.

It seems, nevertheless, that despite the bitter lessons taught by past experience army contractors refuse to learn wisdom. Perhaps the Crimean war was the most striking instance of the shortcomings of army caterers. Our campaign in Cuba was not undistinguished for defects in this respect, and even granting that the outcry raised with regard to embalmed beef was not altogether justified by facts, still that the said beef was not free from suspicion cannot be in truth asserted by the most rabid partisans of that department of the United States government in whose hands the feeding of its soldiers was placed. One might, therefore, have reasonably concluded that the British government, with so many and so recent examples of the evils attending careless methods of commissariat management generally, and the providing of improper food in particular, would have insisted on the supply for South Africa being strictly inspected. Such, however, has not been the case, and the news has come that already, and before leaving port, fifteen thousand pounds of canned meat has been condemned and ordered to be dumped into the sea. The report states that the tainted meat was procured chiefly from colonial sources. The main obstacles in the way of the British army making rapid progress up country after landing in Africa will undoubtedly be the immense difficulties of transport. Ladysmith, whose relief will naturally be the first object of Sir Redvers Buller, is one hundred and eighty-nine miles from Durban; the former town is thirty-two hundred and eighty-four feet above sea level and connected with Durban by only a single line of railway. It is estimated that the invading army will require at least three hundred tons of provision daily, and, in addition to this, sick, wounded, and ammunition must be conveyed. Needless to say, the railway's carrying powers will be wholly inadequate to meet this strain. Consequently wagons will have to be used along tracks which, as the rainy season has set in, are now almost impassable. Mules and trek oxen, the only animals available for traction purposes, are, owing to rinderpest, scarce in South Africa, although fifteen thousand mules have been purchased in Spain, France, the United States, and elsewhere. It will thus be seen that the problem set the British army medical authorities with regard to the removal of their sick and wounded will be one hard to solve successfully. This is the dark side of the picture. The reverse indicates that the efforts being put forward by the army medical department are energetic and strenuous, and if loyally seconded by the transport department there would seem to be every reason to hope that the sick and wounded will fare as well as the exigencies of such a campaign will permit. *The Lancet*, referring to this matter, says: "With regard to the feeding and supplies for the army and its hospitals, enormous difficulties have to be overcome in a campaign of this character. Transport is one of these, and we hope that the medical service will be amply supplied with transports of all kinds. The pivot on which field medical arrangements depend in modern warfare is transport for the systematic and easy movement of the wounded from the fighting front along the lines of communication to the base."

A rest camp and a remount depot have been prepared at Durban, and camps of a similar nature will be established at suitable points. The supply of hospital ships will be large enough, one would think, to meet all requirements. Two of these vessels will be in the roadstead, one stationary, while the other will move backward and forward so that the patients on board may enjoy the benefits of fresh breezes. The central Red Cross committee has decided on sending a fully equipped hospital train, which will doubtless prove of incalculable advantage as a means of conveying the sick and wounded with rapidity and with comfort. On the whole, and when taking the fact into consideration that the British government was on its own showing hardly prepared for a war of such magnitude as the South African struggle promises to be, the exertions now being made on all hands to place every department on a smoothly working footing augurs well for the final result. One feature of the Transvaal war must be viewed with peculiar satisfaction by the army medical department of this country. The feature to which reference is made is the adoption by the British army authorities of hospital ships and trains, a system inaugurated with such splendid effect in our war with Spain.

## MILK AND TUBERCULOSIS IN CHILDHOOD.

THE contest over the question as to whether or not tuberculosis might be transmitted to man in his food has now for several years been carried on, and it would seem that to the majority of physicians the conviction has been borne to their minds that such is indeed the case. With regard to the disease as it affects infants, the theory that infection is caused by means of milk is regarded by many as quite an established fact. The evidence in favor of this theory is *prima facie* a strong one. Tuberculosis is a common disease with the very young; their food is principally milk, and cows are notoriously subject to tuberculosis. Again, in cases of infantile tuberculosis the intestines are usually found to be affected. Dr. Sidney Martin, in Allbutt's "System of Medicine," says: "To the ingestion of milk is no doubt to be ascribed practically all the cases of intestinal tuberculosis and of tuberculous peritonitis that occur in childhood." Dr. Osler is not so decided on the point, and writing on the subject in Starr and Westcott's "Diseases of Childhood," says: "That tuberculosis may originate in the alimentary canal is shown experimentally by the feeding of guinea-pigs with cultures of the bacillus and the feeding of calves and pigs with the milk of tuberculous animals. . . . That the intestinal lesion may be primary in children is acknowledged. The comparatively large number of children with caseous foci is suggestive. On the other hand, instances of primary intestinal tuberculosis are not very common." Dr. Sheridan Delépine is firmly of the opinion that it is through the intestine that tuberculosis attacks the body, and is positive that, whatever may be asserted to the contrary, the consumption of tuberculous milk

is attended with serious danger. He gives instances coming under his immediate notice, in which it was distinctly proved by post-mortem microscopical examination of children whose mesenteric glands showed clear tuberculous lesions. Dr. Sims Woodhead published in 1889 statistics pointing out that tuberculosis in children was due to ingestion of tubercle bacilli, probably along with milk from tuberculous animals, and furthermore drew attention to the fact that during the first year of life the number was comparatively small, but that from one to five and a half years there was a rapid rise which could be accounted for only on the supposition that infective material made its way—in children especially—into the alimentary canal, and thus set up intestinal and mesenteric tuberculosis. The proof, indeed, of intestinal tuberculosis in children being caused by infected milk is, if not overwhelming, at least extremely strong. However, many experienced pediatrists refuse to accept this theory as conclusively demonstrated. Among these is Dr. George F. Still, one of the physicians to the Great Ormond Street Hospital for Sick Children, London. Dr. Still contributed a paper on the matter at the recent meeting of the British Medical Association, in which, speaking of the mode of infection in childhood, he said: "It is evident that the main incidence of tuberculosis corresponds more or less exactly with the period at which milk forms or should form the chief article of diet. The suggestion that milk contaminated with the tubercle bacillus is the cause of this frequency follows as a matter of course. At first sight such a view appears extremely probable. . . . But further inquiry is needed before any conclusions can be drawn from these premises." Dr. Still then proceeds to show that although tuberculous lesion of the intestines and mesenteric glands in infancy and childhood is a well-known fact, the frequency of its occurrence is no evidence of its being the most common source of infection, and in addition that pulmonary lesions would seem to be much more frequent than intestinal, as evidenced by statistics. He is of the opinion that the prevalence of intestinal lesions is due to the swallowing of tuberculous sputum, and that, with a primary infection of the lung, tubercle bacilli are constantly being swallowed in large numbers, so that secondary infection of the intestine is extremely likely to occur. He would prefer to be guided by the condition of the lymphatic glands, which he considers the most reliable index of the sequence of infection, and considers those of the mediastinum the ones most commonly first infected. Another channel of infection to which Dr. Still draws attention is that of the teeth, and thinks that carious teeth, especially in a child predisposed to tubercle, may be a primary cause of infection. These are the conclusions which Dr. Still draws from his observations:

1. The commonest channel of infection with tuberculosis in childhood is through the lung.

2. Infection through the intestine is less common in infancy than in later childhood.

3. Milk, therefore, is not the usual source of tuberculosis in infancy, perhaps owing to the precautions taken in boiling, sterilizing, etc.

4. Inhalation is much the commonest mode of infection, and especially in infancy.

5. The overcrowding of the poorer population in the large towns is probably responsible for much of the tuberculosis of childhood, and prophylaxis must be directed to the prevention of this overcrowding, the improvement of ventilation, and the inculcation of the extreme importance of fresh air during the earliest years of life.

It may be that the danger to children of drinking milk from a tuberculous cow has been somewhat exaggerated, and there can be no doubt that good ventilation and fresh air are an absolute necessity to infants predisposed to tuberculosis; but it must not be forgotten that, though the most frequent form of primary consumption is through the lungs, infection through the intestine is also very common, and therefore in order to minimize this source of danger every effort should be made by health authorities to insure a pure milk supply.

## THE INFECTIOUSNESS OF RHEUMATISM AND CHOREA, AND THE RELATION BETWEEN THEM.

It is pretty generally believed that acute rheumatic polyarthritis is an infectious disease, even if of multiple origin. Numerous observers have found micro-organisms in the lesions of the disease and of its complications, but these have differed among themselves and it has not, heretofore, been possible to cultivate the micro-organisms artificially and with them again to generate acute polyarthritis. For a long time some relation has been thought to exist between acute rheumatism and chorea, the latter affection not rarely following the former, both prevailing at corresponding seasons and both being often complicated by endocarditis. Chorea also is coming gradually to be looked upon as an infectious disease, but concerning its bacteriology little is as yet known. Whether chorea is dependent upon the same causes as acute rheumatism or upon allied causes must be considered as yet merely a matter for speculation. An important contribution to this most interesting subject has recently been made by Westphal, Wassermann, and Malkoff in the *Berliner klinische Wochenschrift*, No. 29, 1899. These observers report a case of acute articular rheumatism followed by chorea and complicated by endocarditis and nephritis, in which they succeeded in isolating from the blood, the brain, and the endocarditic vegetations a micrococcus susceptible of culture and capable of inducing polyarthritis when inoculated into lower animals. The patient was a girl nineteen years old, who in the sequence of an attack of acute articular rheumatism developed chorea, with general movements, delirium, elevation of temperature, acceleration of pulse and collapse, followed by death. Post-mortem examination disclosed the presence of fine, delicate endocarditic vegetations upon the mitral leaflets, as well as recent parenchymatous nephritis. From the blood, the brain, and the valve-leaflets was isolated a micro-organism, injection of which in small quantities into the blood-vessels was

followed in animals by the development of high fever and multiple arthritis, usually terminating fatally. The affected joints presented evidences of inflammation, and in the exudate was found the micro-organism already mentioned. Injection of this after culture again induced acute multiple arthritis. The micro-organism is a streptococcus, although in the tissues and in the blood it may appear as a diplococcus, and it may be the same as that found by other observers in the vegetations of endocarditis, but not subjected to culture and inoculation. Its growth requires a higher degree of alkalinity of the culture medium than usual and a larger amount of peptone.

## DOES IT PAY?

In the course of his professional life many a man must pause and ask himself this question. In the *Cincinnati Lancet-Clinic* of September 9th there are two communications, one entitled "Does the Practice of Medicine Pay?" in which the writer, Dr. Monroe, of Louisville, takes a rather pessimistic view, dwells upon the many hardships of a doctor's life, and dismisses the subject with the words: "Therefore, taking everything into consideration, I think I am perfectly safe in saying, in closing this paper, that it does not pay financially to be a physician."

The second paper has for its caption "Does It Pay to Live?" in which the intellectual pleasures constituting

"The soul's calm sunshine and the heartfelt joy"

are dwelt upon, and it is pointed out that there are other objects in life beside and beyond those associated with finance.

This writer, Dr. Woodruff, believes that no greater reward can come to a physician than the ability to look back upon time well spent and the consciousness of good example stamped upon the community. He says: "The opportunities of relieving suffering and inspiring hope in the despondent are so numerous in the daily rounds of a doctor, that any physician who has spent his life in the conscientious discharge of his duties may answer the question in the affirmative."

But after all it is the individual point of view. "As a man thinketh in his heart, so is he."

**The Old, Old Story.**—A correspondent of the *New England Medical Monthly*, writing of one of the latest serums for the cure of insanity, old age, and many other ills, says: "Whatever may be the merits of the so-called —— lymph, it is being exploited in a most unprofessional way. Licenses to use it are issued for $100 to one physician in a locality, who must pay three cents a drop for the lymph, and give the promoters, or company, or whatever it may be, one-third of all his earnings in using the lymph, and is obligated by contract to sell his services at a fixed price. There is said to be a clause by which the poor are provided for." Whatever the therapeutic virtues of the serums, they one and all seem to arouse in their discoverers the gold itch in a most acute form.

## News of the Week.

**Philadelphia County Medical Society.**—At a stated meeting held November 8, 1899, Dr. Mordecai Price read a paper entitled "Treatment of Appendicitis, and its Great Mortality," and Dr. Charles W. Dulles read a paper entitled "Medical Journal Ethics."

**Honored by His Colleagues.**—A well-attended dinner was given on November 7th, at the University Club, Philadelphia, in honor of Dr. Alonzo E. Taylor, recently elected professor of pathology in the University of California, and formerly assistant director of the Pepper Laboratory of Clinical Medicine.

**Philadelphia Pediatric Society.**—At a meeting held November 10th, Dr. Thomas Morgan Rotch, of Boston, read a paper entitled "Some of the Difficulties in Prescribing and Modifying Milk for Infants," in which he dwelt upon the importance of securing proper proportions of fat, proteids, and sugar, and of insuring a maximum freedom from bacteria. At the close of the meeting a reception was held in Dr. Rotch's honor.

**Anglo-American Nursing Home in Rome.**—We learn from the *British Medical Journal* that the proposal to establish an Anglo-American Nursing Home in Rome is likely to be carried out. The need for such an institution has been felt by many British and American practitioners in Rome. A sum of £1,000 has been subscribed for a building fund, and negotiations are on foot for the purchase of a house. The home when established will receive cases of illness of any kind, including typhoid fever.

**College of Physicians of Philadelphia.**—At a stated meeting held November 1, 1899, Mr. Frederic E. Ives, by invitation, demonstrated his system of color photography, especially in its application to medicine. The principle of the process consists essentially in obtaining photographs in triplicate through red green, and violet glass respectively. By the superposition of these the original colors are reproduced. Beautiful pictures of fibroid uterus, carcinoma of the breast, panophthalmitis, hypertrophied prostate, and surgical kidneys, exhibiting the normal colors and appearances, were shown. Dr. R. C. Cleeman described the circumstances attending the admission of an immigrant suffering from typhus fever, who died subsequently at the Municipal Hospital presenting characteristic lesions.

**The Pan-American Medical Congress.**—Three years ago at Mexico it was decided to hold the next Pan-American Medical Congress at Caracas in December of the present year. Some time ago the Venezuelan national committee in charge of the arrangements for the meeting decided to postpone the congress for a twelvemonth. But owing to the generally unsettled and revolutionary state of Venezuela, it is doubtful whether a meeting can ever be held there, and moreover the hotel accommodations in Caracas are utterly inadequate for a quarter of those who attended the

meeting in Mexico. In view of these facts it would seem not inadvisable for the international committee to withdraw the acceptance of the Venezuelan invitation, and select some other place—Montreal or one of the larger cities of South America, in some country where the political conditions are fairly stable, and where there would be a reasonable certainty of holding the meeting at the appointed date.

**The Oklahoma Territorial Medical Association** will meet in Guthrie on November 23d.

**A Maternity Hospital in Montreal.**—Lord Strathcona and Mount Royal has contributed $10,000 toward the fund for the erection of a building for the Montreal Maternity Hospital. The new governing board will have representatives from McGill University and the Royal Victoria and General hospitals.

**The Loomis Sanatorium.**—It is expected that the new administration building of this sanatorium, to replace the one which was totally destroyed by fire on October 14th, will be completed within a few months. The Casino has been adapted temporarily to the purposes of the administration. No injury was done by the fire to any of the patients' cottages.

**The Sale of Poisons.**—The president of the New York boardof health has taken action looking to a stricter enforcement of the law regarding the sale of poisons, being led thereto by the many cases of suicide, especially among women, committed on impulse, and which would probably never have occurred had the impossibility of procuring the poison given time for reflection.

**Pathological Society of Philadelphia.**—At a stated meeting held November 9, Dr. P. W. Darrah read a paper entitled "An Experimental Study of Illuminating-Gas Poisoning." He related that dogs exposed to the action of illuminating-gas could be resuscitated by transfusion of arterial blood from another animal of the species, while inhalations of oxygen and subcutaneous and intravenous injections of hydrogen dioxide and saline solution failed. Dr. F. A. Packard exhibited the spinal cord from a case of cerebro-spinal meningitis. Dr. M. H. Fussell exhibited kidneys, heart, liver, spleen, and lungs from a case of chronic parenchymatous nephritis, cardiac dilatation, nutmeg liver, perisplenitis, and pulmonary hypostasis. Dr. A. E. Blackburn exhibited a specimen of carcinoma of the stomach, involving the pancreas, omentum, and liver. Dr. A. V. Meigs presented a communication entitled "Endophlebitis," and exhibited sections showing enormous hyperplasia of the middle coat especially of a peripheral vein, with almost obliteration of the blood-channel. Dr. J. D. Steele presented a communication entitled "Endothelioma of the Retroperitoneal Space," and exhibited a section illustrating the histological features. Drs. J. H. Musser and D. L. Edsall exhibited specimens of carcinoma of the mediastinal glands, and of the lower lobe of the right lung, with carnification of the upper lobe and dilatation of the stomach. During life there had been enlargement of the supraclavicular and of the axillary glands, copious effusion into the right pleural cavity, and a tumor was found in the pyloric region which was found to consist of the thickened pylorus surrounded by a ring of enlarged glands. It was thought the pancreas also was involved, but the liver was free. The retroperitoneal glands above the pancreas were also the seat of disease.

**A Proposed Epileptic Colony in Virginia.**—We learn from the *Virginia Medical Semi-Monthly* that a commission was appointed by the recent General Assembly to study the subject of a State colony for the care of epileptics. This commission—consisting of Drs. George W. Le Cato, of Accomac County, William F. Drewry, of Petersburg, Col. C. E. Vawter, and Mr. W. F. McRae—is looking for a suitable farm, to be recommended for purchase by the State for the purpose indicated, and is estimating every detail of probable expense, so as to be ready to have an act enacted by the legislature next winter establishing such an epileptic colony.

**Yellow Fever** is dying out in Key West and Miami, Fla. Two cases and one death were reported at Port Tampa on November 10th, and the usual quarantine has been established against the place, but because of the lateness of the season no alarm is manifested. At a meeting of the Orleans Parish Medical Society on November 11th, there was a discussion on the recent epidemic in that city, and some of the speakers held that the disease had not been yellow fever, but malaria. Reported bacteriological examinations, it is said, failed to reveal the presence of the bacillus icteroides of Sanarelli, while on the other hand the plasmodium malariæ was frequently found.

**Overcrowding on the Transport "Tartar."**—The report of the board of inquiry regarding the treatment of the sick on the *Tartar*, which arrived recently at San Francisco from Manila, criticises the placing of so many sick troops on a transport which had accommodations for only twenty-six emergency sick. The volunteer regiments that embarked at Manila to return to the United States had many sick among them. It is said that it was the duty of the regimental surgeon to leave in the Manila hospitals those men who were ill, and not to place them on the *Tartar*, as was done. There are hospital ships at Manila for the work of bringing home the sick, and it is not necessary to place them on the regular troop-ships. It is not likely that any action will be taken, however, as the surgeon of the regiment and nearly all of its officers have been mustered out of the service of the United States. Orders have been given that in the future a regular army officer stationed at Manila shall see that none of the transports leaves the Philippines with men too ill to be transported in the regular troop-ship.

**The Medical Society of Virginia.**—At the thirtieth annual meeting of this society, held in Richmond, October 24th, 25th, 26th, and 27th, the following officers were elected: *President*, Dr. Hugh T. Nelson, of Charlottesville; *Vice-Presidents*, Drs. Southgate Leigh, of Norfolk, S. T. A. Kent, of Ingram, and R. J. Hicks, of Warrenton; *Recording Secretary*, Dr. Landon B. Edwards, of Richmond; *Corresponding Secretary*, Dr. John

F. Winn, of Richmond; *Treasurer*, Dr. Richard T. Sty'l, of Newport News. Dr. John P. Upshur, of Richmond, was appointed to deliver the annual address, and Dr. Stuart MacLean, of Richmond, to open the general discussion on "Malaria." The next meeting will be held in Charlottesville.

**The Sanitary Condition of a Railroad.**—After a period of rest and apparent unconcern, the New York City board of health has again awakened to the dangers which menace the health of the travelling public in the Borough of Manhattan. An examination was made some time ago regarding the standing of the elevated road, the soundness of its structure, and the paint on its cross beams, but the result of this investigation was unsatisfactory; at least there was no visible result either in the condition of the road or in the value of its securities. The present examination concerns the condition of the cars, which is said to be unsanitary. To the ordinary citizen there is no apparent difference, as regards insanitary conditions, between the elevated cars and those of the surface roads.

**Medical Matters in the South African War.**—Three surgeons and five trained nurses for the hospital ship *Maine*, which is being fitted out by American-born women for service in South African waters, sailed from this city on Sunday last. The surgeons were Drs. G. E. Dodge and H. H. Rodman, of New York, and C. H. Weber, of Philadelphia. Surg.-Col. F. H. Hensman, of the British army, has been appointed chief medical officer in charge of the *Maine*. One of his assistant surgeons will be English, the others Americans. With the staff sailing Sunday was taken an ambulance, selected as the latest and best product of army experience, which was the gift of Mrs. Whitelaw Reid, to whom was entrusted the work of selecting the nurses. About thirty more nurses, both men and women, will be sent next week.—The Duke of Newcastle has undertaken to pay all expenses necessary to the fitting out of the second hospital ship, the *Princess of Wales*, formerly the *Midnight Sun*.—The statement that the British artillerists fired upon a Red Cross ambulance turns out to be true, but according to the account given by a Boer clergyman the occurrence was accidental. The ambulance was close to the firing line, and was hidden from the view of the British. One shot went through the ambulance, but as soon as it was seen what had been done, the British ceased firing in that direction. The persistent reports that the Boers had fired upon the Red Cross flag are doubtless explainable in the same way.—Scarlet fever has broken out in the barracks of the Horse Guards, Blues, and this will probably cause a postponement of their departure for South Africa.—A woman physician of London wrote to the Marquis of Lansdowne, Secretary of State for War, volunteering her services as a physician in South Africa. In his reply the secretary expressed his appreciation of the offer, but said that he was not prepared as yet to allow women physicians to join the forces in the field.—An appeal has been published in Vienna for subscriptions in aid of the Boer wounded, and several surgeons have left that city to join the medical staff of the Transvaal army. The Italian Red Cross Society has sent medicines to the Boers, and will provide fruit for the wounded on the British side.—It is said that the men wounded in the recent battles recover with marvellous rapidity, many reporting for duty within two weeks after being shot. The rifles of the Boers are Mausers, and the wounds made by them are small and clean, and, unless a vital part is pierced, heal *cito, tuto et jucunde*. This is similar to our own experience in Cuba. Wars will never cease if something is not done to make them more sanguinary and horrible, and therein lies the mistake of peace conferences and Red Cross conventions.

**The Plague** has reached Lorenzo Marquez on Delagoa Bay, near which it has prevailed for some time past. In reporting the appearance of the plague in Paraguay, the Buenos Ayres *Herald* suggests that it may be merely a visitation of the pigue or sand-flea, the bite of which is exceedingly poisonous and often gives rise to glandular swellings.

**Craig Colony Prize for Original Research in Epilepsy.**—Last year Dr. Frederick Peterson, president of the board of managers of the Craig Colony for Epileptics, offered a prize of $100 for the best original contribution to the pathology and treatment of epilepsy. The seven papers received were submitted to three members of the New York Neurological Society, who decided that no award should be made this year. Some of the essays submitted failed to comply with the conditions of the competition, others were more limited in scope than a successful essay should be. The prize of 1899 not having been awarded in accordance with the report of the committee, Dr. Peterson now offers a prize of $200 for the year 1900 under similar conditions. This sum will be awarded to the author of the best contribution to the pathology and treatment of epilepsy. Originality is the main condition. The prize is open to universal competition, but all manuscripts must be submitted in English. Each essay must be accompanied by a sealed envelope containing the name and address of the author and bearing upon the outside a motto or device which is to be inscribed upon the essay. All papers will be submitted to a committee, consisting of three members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the board of managers of the Craig Colony, October 9, 1900. Manuscripts should be sent to Dr. Frederick Peterson, No. 4 West Fiftieth Street, New York City, on or before September 1, 1900. The successful essay becomes the property of the Craig Colony and will be published in its medical report.

**The St. Louis Academy of Medical and Surgical Sciences** held its annual meeting on November 7th and elected the following officers: *President*, Dr. James Moores Ball; *Senior Vice-President*, Dr. William Porter; *Junior Vice-President*, Dr. H. G. Nicks; *Secretary*, Dr. R. B. H. Gradwohl; *Treasurer*, Dr. Emory Lanphear; *Orator*, Dr. J. C. Murphy; *Curator and*

*Librarian*, Dr. Robert Edward Wilson. At the same meeting Dr. Lanphear read a paper on "Some Practical Points in the Treatment of Diseases of Women," and Dr. B. S. Simpson presented his thesis, "Report of a Case of Exophthalmic Goitre Treated by Sympathectomy."

**Ptomain Poisoning.**—Fifty members of the Forty-second Volunteer Infantry at San Francisco were recently the victims of ptomain poisoning caused by hash made with tainted meat.

**Smallpox in Chicago.**—Several cases of smallpox have been brought into Chicago from Storm Lake, Iowa, where the disease exists among the laborers on the railway.

**The Medical and Chirurgical Faculty of Maryland.**—The programme of the Medical and Chirurgical Faculty, the State society of Maryland, to be held at Westminster, November 14th, is as follows: After an address of welcome, to which the president, Dr. G. Birnie, will reply, the first paper will be by Dr. E. F. Cordell, on "The Medical and Chirurgical Faculty's Contribution to the Welfare of the State." Dr. William Osler will then speak of the "Home Treatment of Consumption," which paper will be discussed by Dr. C. S. Millet, of Brockton, Mass. The title of a paper by Dr. James H. Billingslea, of Westminster, has not yet been announced, but it will be followed by an article by Dr. Charles R. Foutz, of Westminster, on "An Interesting Case of Cystitis." "Excision of the Pylorus for Carcinoma, with Report of a Case," will be the subject of Dr. J. H. Branham's paper, and Dr. J. C. Hemmeter will be heard from on "The Use and Abuse of Hydrochloric Acid in Gastric Disease." After luncheon is served, Dr. A. D. McConachie will read a paper on "The Naso-Pharynx in Relation to Aural Disease," and Dr. H. H. Young one on "The Recent Methods of Treating Hypertrophied Prostate by Electro-Cautery." Dr. Simon Flexner and Dr. L. F. Barker, who have just returned from the Philippines, will then read articles on "The Medical Conditions in the Philippines and India"; while the concluding papers will be on "Typhoid Fever in the Country Districts," by Drs. J. S. Fulton, C. Hampson Jones, C. M. Ellis, and V. M. Reichard.

**College of Physicians of Philadelphia; Section on General Medicine.**—At a stated meeting held November 13th, Dr. W. G. Spiller exhibited a case of post-hemiplegic hypertonicity in a girl aged about seventeen years, who had a convulsion at the age of three months and presented paresis and slightly retarded development of the right side of the body, with marked flexor tonic spasm of the right hand, at times relaxing, with average intelligence and without aphasia. Dr. Spiller exhibited also a case of Jacksonian epilepsy with hemianopsia and monohypertonia, occurring in a young man who, in diving in water, had struck his head on a brick and had been trephined, but without relief. Dr. F. A. Packard reported two cases of traumatic tetanus with somewhat unusual features. One occurred in a boy aged nine years, who was injured by the discharge of a toy pistol. Death ensued in spite of treatment with tetanus antitoxin, physostigmine, chloral, bromide, and oxygen inhalations. The other followed a lacerated wound of the forehead by the twig of a tree, and symptoms of facial palsy appeared concurrently with those of tetanus. Death resulted in spite of frequently repeated full doses of carbolic acid. Dr. D. J. McCarthy read a paper entitled "Narcolepsy," in which he contended that the condition is merely a symptom which may attend a number of conditions, such as hysteria, epilepsy, intoxications, etc. Dr. J. D. Steele reported a case of typhoid fever with concurrent malarial infection. The chills and the malarial pyrexia appeared during the typhoid defervescence, and seemed to dissipate the remnant of typhoid fever.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending November 11, 1899. November 3d.—Passed Assistant Surgeon R. G. Brodrick ordered to Washington, D. C., November 17th, for examination for retirement, and then home and to wait orders. November 4th.—Surgeon O. D. Norton detached from the *Ranger* and ordered to the *Monadnock* via the *Solace*. Passed Assistant Surgeon R. K. Smith detached from the naval hospital at New York, and ordered to the naval hospital at Mare Island, Cal. Assistant Surgeon O. M. Eakins ordered to the Naval Academy. Assistant Surgeon W. M. Wheeler ordered to the naval hospital at New York. Assistant Surgeon H. E. Odell detached from the naval hospital at Mare Island, Cal., and ordered to the *Ranger*. November 6th.—Medical Director R. A. Marmion promoted to medical director. Medical Inspector M. H. Simons promoted to medical inspector. Surgeon L. G. Heneberger detached from the *Indiana* November 10th, and ordered home and to wait orders. Surgeon W. A. McClurg ordered to the *Indiana* November 10th. Passed Assistant Surgeon G. D. Costigan promoted to passed assistant surgeon.

**Surgeon-General Sternberg's Report,** which has just been made public, dwells at length upon the health of the troops in the tropics and at home, the casualties and losses in battle and in hospital, and the care of the sick and wounded. The number of deaths, including the regulars and volunteers from May 1, 1898, to June 30, 1899, is given as 6,619. Of these, 496 men were killed in battle and 216 by accident, 202 died from gunshot wounds, 2,774 from typhoid fever, 476 from malarial fever, 359 from pneumonia, 342 from diarrhœa and dysentery, and 185 from yellow fever. General Sternberg attributes the prevalence of typhoid fever to the unsanitary condition of many of the camps where the disease became epidemic, and the failure to suppress the disease to the inexperience of regimental and line officers and want of discipline among the men. He says it has been his endeavor that the sick and wounded should be supplied with every comfort and restorative, and the surgeons with every appliance that modern science could suggest in the treatment of disease and injury. Concerning the

preparation for the future, he remarks that "the value of the aphorism, 'In time of peace prepare for war,' has received additional support during our recent experience. This preparation should include a corps of trained medical officers larger than is absolutely necessary for the army on a peace basis, and systematic instruction in military medicine and hygiene for the medical officers of the National Guard, as well as for those of the regular army; also instruction of line officers in the elements of hygiene, and especially in camp sanitation. It should also include the establishment of camping grounds in various parts of the country, having an ample supply of pure water, a proper system of sewers, etc. If our volunteers could have been assembled in such camps during the late war a saving in lives and money would have resulted, which would, without doubt, have demonstrated the economy of such preparation for war in time of peace."

**The Late Dr. Hamilton Mailly.**—The following resolutions were adopted at a meeting of the Bridgeton, N. J., Hospital staff, on November 1, 1899:

"*Whereas*, The death of Dr. Hamilton Mailly has taken from the hospital staff of the Bridgeton Hospital one of its most valued members; and

"*Whereas*, During the time that Dr. Mailly had served on the staff he had by his professional ability and attainments, by his unfailing courtesy and his always ardent devotion to what he believed to be right, given character and dignity to the honorable profession of which he was a member:

"*Resolved*, That the staff place on record their sincere regret at his untimely death, as well as their high appreciation of his many qualities of mind and heart which led them to respect him as a man and honor him as a physician.

"John H. Moore, David H. Oliver, Ellsmore Stites, Committee."

**The Death of Dr. Edward Bleecker.**—At a special meeting of the Flushing Hospital staff, held on November 6, 1899, in memory of their late associate, Dr. Edward Bleecker, of Whitestone, the following minute was unanimously adopted:

"In the sad Providence which has removed from among us our late associate we hasten to record this tribute of our esteem and affection as a meagre memorial to his high character and sturdy manhood. Had Dr. Bleecker sustained no other relationships, his commanding position as a leader of men, his numerous and honorable official positions, and his wide sympathies with all that affected the people among whom his life was spent, were enough to mark his career as aside and above that which falls to most men.

"As his professional associates we add our hearty testimony to his varied and rare accomplishments as a physician. Removed at a time when all his powers were at the climax, wise in counsel and always resourceful in expedient, he won our admiration and commanded our respect in emergencies where unfaltering courage could alone save life. To us his untimely death brings a sense of irreparable loss only less than to those of his immediate family. To them we extend our deepest sympathy in a bereavement that, after all, only time can assuage and heal."

**Obituary Notes.**—Dr. Walter J. Hoffman, United States consul at Mannheim, Germany, died at his home at Reading, Pa., on November 8th, at the age of fifty-three years. He was graduated from Jefferson Medical College in 1866, and at the outbreak of the Franco-Prussian War received a commission as surgeon in the Prussian army. After returning to America he was, in 1871, made an acting assistant surgeon in the United States army, and naturalist to the expedition for the exploration of Nevada and Arizona. In 1872 he was ordered to the military post at Grand River agency, Dakota, where he served as post-surgeon and prosecuted researches in the language and mythology of the Dakota Indians. He accompanied many expeditions, and later became connected with the Smithsonian Institution at Washington. He was for a number of years associated with the Bureau of Ethnology, and was a recognized authority on this subject. He devoted many years to the study of the Indians, concerning whom he wrote a good deal, and he was admitted into a number of tribes. He was variously honored by the Emperor of Germany, the King of Norway and Sweden, and other important personages and bodies.—Dr. Dilwyn P. Pancoast, of Mullica Hill, N. J., died in Camden, N. J., on November 4th, at the age of sixty-three years. He was graduated from the medical department of the University of Pennsylvania in 1856, entering the army in 1863, and remaining in the service until the close of the Rebellion in 1865.—Dr. W. H. Beane died at Middletown, Pa., on November 8th, at the age of sixty-two years.—Dr. John A. McCreery died at his home in this city on November 11th. He had been in poor health for several months. Dr. McCreery was born in this city on January 6, 1850. He was graduated from Bellevue Hospital Medical College in 1871, and in 1874 received the degree of M.R.C.S., London. He began practice in this city in 1875. He was visiting surgeon at St. Vincent's Hospital, and was a member of the County Medical Society, the Academy of Medicine, and the Pathological Society. A widow and three children survive him.—Dr. James M. Morrison, of Baltimore, Md., died at his home in that city on November 13th, from injuries received at the hands of two burglars. He discovered them in his house one night about two weeks ago and attempted to drive them off, but they threw him down and stamped on him most brutally. Dr. Morrison was born in Maryland in 1837, and was graduated from the University of Maryland School of Medicine in 1859. At the beginning of the Civil War he received a surgeon's appointment and was commissioned in the Fourth Pennsylvania Cavalry. He was afterward transferred to the Forty-eighth Pennsylvania Infantry, and served with distinction throughout the war, and took an active part in some of the greatest engagements. Soon after the close of the war he was commissioned in the regular army. He was in Custer's command at the time of the latter's death, but left the army soon after and took up private practice in Baltimore.

## Therapeutic Hints.

**Treatment of Appendicitis by Absolute Repose.**—Dr. Romme (*Presse Médicale*) describes the method of treatment of appendicitis at the "Bethanien" Hospital of Berlin, the principle of which is complete rest. After the acute symptoms have subsided he recommends the removal of the appendix.

**Gastric Ulcer.**—Absolute rest in bed, nourish by rectal enemata, and apply cold compresses to the stomach. Codeine by the mouth, or morphine hypodermatically to lessen peristalsis and partly to narcotize the patient, should be given; also, the alkaline mineral waters, or five grains of bicarbonate of sodium, followed by a little whiskey and milk.—J. C. Wilson.

**Quinine Hypodermically.**—It has long been a desideratum in the practice of medicine to procure a solution of quinine which can be administered hypodermically without causing irritation to and blistering of the cuticle. I have for the past two years been using a fifty-per-cent. solution, dissolved in muriatic acid, which produces no ill effect whatever, and also find excellent results from giving the same liquid in capsules. Muriatic acid being native to the stomach assimilates more readily than either tartaric or sulphuric acid, and the quinine is dissolved more rapidly and thoroughly than it can be with the other two acids. I have used this solution (fifty per cent. of quinine in muriatic acid) in unusually large doses without any of the uncomfortable results generally attending the use of sulphate of quinine, giving as much as thirty grains in capsules without any resultant headache or ringing in the ears. The quinine acts directly and happily, administered in capsules holding ten grains each. I therefore recommend the formula to the profession used as above stated.—N. S. Lincoln, M.D., Washington, D. C.

**Treatment of La Grippe.**—Absolute and prolonged rest in bed until after all fever has disappeared and the principal symptoms have been ameliorated, notably pulmonary manifestations; an exclusive liquid diet, consisting of milk, coffee, mild stimulants, and hot drinks. The coffee is useful as a diuretic and to antagonize nervous depression. Gargling with some mild antiseptic, and spraying out the nose with a liquid alboline containing three to six grains of menthol to the ounce, is advised. In symptoms of great nervous depression, sore throat, hoarseness, fever, and other manifestations of respiratory difficulty, quinine is the remedy, the hydrochlorate being preferred, given in doses of ten to fifteen grains three times in twenty-four hours in cachets. Should the stomach be intolerant, it may be given by the rectum, dissolved in the proper quantity of hot water, or suppositories of hydrochlorate of quinine may be used. Antipyrin seems to be of value in combating fever and quieting pain, but it often is a dangerous remedy in old persons. If the temperature is very high, warm baths, continued for fifteen to twenty minutes, are advisable. To overcome congestion in the pulmonary mucous membranes, from ten to fifteen grains of chloride of ammonium and five to ten grains of Dover's powder may be given in the course of the day. To overcome cough and produce sleep, opium, morphine, or codeine may be used.—*Public Health Journal.*

**Quinine as a Specific in Malarial Hæmaturia.**—Dr. L. G. LeBeuf read a paper at the last meeting of the Louisiana State Medical Society on the subject of quinine in hæmaturia, and reported four cases of the worst type of hæmaturia. He contends that the only specific remedy is to be found in the alkaloids of Peruvian bark. In Louisiana and the South generally the custom is to use turpentine, ergot, strychnine, and counter-irritants, but rarely quinine. In opposition to the various authorities who oppose quinine are all the modern text-books and especially the writings of Hare in the Medical Record, and James Tyson. To-day, with the use of the microscope and urinalysis an exact diagnosis can always be arrived at, and while the experience of others shows that quinine should be exhibited carefully, as it is an irritant to the genito-urinary tract and produces some peculiar metabolism in the circulation, its use should not be condemned, but on the contrary it should be administered judiciously, and a middle course adopted to avoid possible dangers.—C. Jeff Miller.

**Urinary Infection—Its Prevention.**—Dr. J. Henry Dowd (*Buffalo Medical Journal*, May) writes as follows: "Conscientiously, I cannot recommend internal medication for the destruction of bacteria developing along the genito-urinary tract; furthermore, urinary antiseptics have been overestimated, except in tuberculous conditions, where creosote or its derivatives will, to a certain extent, prevent the growth of these specific bacteria. To be sure, drugs recommended for this purpose, when placed in freshly passed urine, will keep it for a longer time without other development than if no drug was used, but the same drug passing through the system, meeting as it does the different chemical substances, to my thinking, is so changed that when it reaches the urine the power of bacterial destruction is lost. Bacteriuria has a definite cause; discover and remove this, and these germs will disappear from the urine. Of the numerous cases which I have been called to operate upon for retention, extravasation, and the like, with but an hour's notice, my results have been just as good as though these patients had been medicated for two or three days previously in trying to obtain an impossibility. Remember the fact that it is just as possible to have an antiseptic operation field here as it is for the abdominal surgeon to have the same."

**Treatment of Acute Rheumatism.**—Dr. Henry B. Fahill (*Journal of the American Medical Association*, May 13th) writes as follows: "I venture to outline a routine, which I would apply to a typical case: (1) Empty the bowels thoroughly, preferably with a sharp mercurial. (2) Administer salicylate of soda to its full and analgesic effect; if it is not well borne by the stomach, its equivalent, oil of wintergreen. If it is contraindicated by cerebral conditions use antipyrin, or the coal-tar preparations best adapted. If these are contraindicated by conditions of the heart or nervous system, use opium. At all events, control the pain. (3) As the pain is controlled by such means, aided by local measures, principally heat and immobilization, gradually draw away the salicylic element and saturate the system with alkalies, continued until the active process seems controlled. (4) Finally, while giving alkalies or after it, administer iron, provided the condition of the bowels and liver permits. (5) At all times, and incessantly, strive to promote intestinal hygiene, by mercurial, cholagogue, or saline cathartics."

**Formaldehyde** in four-per-cent. solution, taken by mistake, caused death in a man of twenty-six years, twenty-nine hours after being swallowed. There was early vomiting with traces of blood, and emesis was encouraged by apomorphine hypodermatically. Subcutaneous injections of strychnine with sparteine and nitroglycerin by the mouth did not counteract the signs of heart failure, which showed themselves sixteen hours after the dose had been taken.—*The Medical Press*, September 20th.

**Threadworms.**—In the treatment of threadworms large injections must be used, and in view of the difficulty of dislodging the worms from the appendix, and their possible presence in the small intestine, the injection should be combined with the administration of drugs by the mouth. The vermiform appendix is a common habitat of oxyuris vermicularis in children. —STILL.

**Emetic for Infants.**—

℞ Pulv. ipecac..... 0.50 cgm.
Antimonii et potassii tartrat..... 1 gm.
Oxymel. scillæ..... 10 "
Aq destill..... 20 "
M. S. Teaspoonful every ten minutes until vomiting occurs (for a child from six to ten years of age).

—BAGINSKY.

**Neuralgia.**—

℞ Ext. hyoscyami..... 0.12 cgm.
Ext. valerian..... 0.20 "
Morphin. hydrochlor..... 0.01 "
Pulv. glycyrrhizæ..... q.s.
For one pill. Make xx. S. One morning and night, or not more than three in twenty-four hours.

—BASTIÉ.

**Oxyuris Vermicularis.**—

℞ Tinct. eucalypti..... 5
Tinct. myrrhæ..... 2
Sodii biborat..... 3
Aquæ..... 500
S. As an injection.

**Ankylostoma Duodenale in Infants.**—

℞ Extr. filicis maris..... 2
Ol. ricini..... 10–15
Syr. menth..... 30
To be taken in two doses.

**Tænia Inermis.**—

℞ Pelletierin. sulphat..... 0.40–0.50
Tannin..... 1.20–1.50
Aquæ..... 100
To be taken in two or three doses

—SCHEFFER, *La Méd. Mod.*, September 20th.

**Psoriasis.**—

℞ Sodii arsenit..... gr. i.
Sodii salicylat..... gr. xlv.
Sodii bicarbonat..... ʒ ij.
Syrupi..... ʒ viij.
M. S. A dessertspoonful after each meal.

—BROCQ.

**Thallium**, which has been used in the night sweats of phthisis, has been found in several instances to produce marked falling of the hair. Huchard reports one instance after four doses of gr. iss. each.—GUINARD, *Jour. des Pratic.*

**Urticaria.**—Phosphate of soda in supersaturated solution and in drachm doses. Locally:

℞ Pulv. calamin.,
Zinci oxidi..... āā ʒ iss.
Acidi carbolici..... ʒ ss.
Aquæ calcis..... ʒ ij.
Aquæ rosæ..... ad ʒ iv.
M. S. Apply frequently and freely.

—WOLFF.

**Pain and Tenesmus of Dysentery.**—

℞ Cocain hydrochlor..... gr. i
Ext ergotæ aq..... gr xij.
Aristol..... gr. v.
Ol. theobrom..... q.s
M. et ft. suppos. No. xii. S. One to be applied every hour.

—TAYLOR AND WELLS.

**Strychnine** should be given early in all cases of depression in acute affections, *i.e.*, as soon as the first indication of depression manifests itself, and in sufficient doses to accomplish the purpose. In chronic affections, if it is to be kept up for months, diminish the dose or withdraw when the first symptoms of physiological action manifest themselves.—UPSHUR.

**Cholera.**—

℞ Oil peppermint..... ʒ iv.
Chloroform..... ʒ iv
Fl. ext. ipecac..... ʒ iiiss.
Fl. ext. valerian..... i.–ʒ ij.
Tinct. opium deod..... ʒ iss.
Ether..... ij.
Alcohol..... ʒ vi.
Sherry wine..... sufficient to make ʒ xvi.
M. S. Adult dose is twenty-five to thirty drops, in a small glass of water every twenty minutes, until relief is obtained.

—THIELMAN.

**Fetor of the Breath.**—

℞ Powdered coffee..... 45 parts.
Vegetable charcoal,
Powdered sugar..... each 15 "
Vanilla.
Mucilage of gum arabic..... a sufficiency.
M. Divide into pastilles of gr. xv. each. Five or six to be chewed daily.

—*Journal de Médecine de Paris*, January.

**Liniment for Hemorrhoids.**—

℞ Extr. hamamelidis fl.,
Extr. hydrastis fl.,
Tinct. benzoini comp..... āā ʒ iv.
Tinct. belladonnæ..... ʒ i.
Ol. olivæ carbolisat. (five per cent.)..... ʒ i.
M. S. For inunction two or three times a day.

—ADLER.

**The Best Anti-Fermentative.**—

℞ Ol cajuputi..... gtt. iij.
On sugar. Repeat.

—MURRELL.

**Catarrhal Conjunctivitis.**—

℞ Protargol..... 1–2 gm.
Aq destillat..... 10 "

This makes a caustic solution to be applied with some caution.—A. DARIER.

**Nephritis.**—

℞ Tinct. grindeliæ robust..... 30
Tinct. convallariæ majalis..... 10
Tinct scillæ..... 5
M. S Fifteen drops three times daily.

—IMMERWAHR.

**Malignant Syphilis.**—Inject from twelve to fifteen ounces of Hayem's solution by four or five subcutaneous punctures at intervals of five or six days.

℞ Sodii chloridi..... 7 parts.
Sodii phosphat..... 2 "
Aquæ..... 1,000 "

—AUGAGNEUR.

**Dyspnœa of Fibroid Phthisis.**—

℞ Sodii chloridi..... 10 gm.
Sodii bromidi..... 5 "
Sodii iodidi..... 1.5 "
Aquæ destil..... 100 "
M S. One to three teaspoonfuls daily in milk.

—POTAIN.

**Epilepsy with Weak Heart.**—

℞ Potassii bromidi..... ʒ v.
Syrupi acaciæ..... ʒ i.
Infusi adonis vernalis..... q s. ad ʒ xvi.
M. S Tablespoonful in water after meals.

**Creosote Cachets.**—

℞ Creosoti,
Benzoin..... āā 0.10 cgm.
Pulv. carbo. lig..... 0.60 "

—MAURANGE.

**Incontinence of Urine** in the female due to lack of power in the vesical sphincter is relieved, according to the *Journal of Medicine and Science*, by minim doses of tincture of cantharides well diluted.

# Reviews and Notices.

Interstitial Gingivitis, or So-Called Pyorrhœa Alveolaris. By Eugene S. Talbot, M.D., D.D.S. Philadelphia S. S. White Dental Manufacturing Company. 1899.

This is a much more comprehensive work than one upon the same subject recently reviewed in these columns. The author goes deeper into several of his subjects—notably the pathology. It must not be thought that Rigg's disease interests the dentist alone. It may have a decided influence upon the whole subject of mastication as influencing digestion and nutrition, and upon constitutional disturbances of various natures. The work is well illustrated, and shows much original thought and investigation.

The Hygiene of Transmissible Diseases: Their Causation, Modes of Dissemination, and Methods of Prevention. By A. C. Abbott, M.D., Professor of Hygiene and Director of the Laboratory of Hygiene, University of Pennsylvania. Octavo volume of 311 pages. Illustrated. Philadelphia. W. B. Saunders.

Taken in part from the author's lectures at the University of Pennsylvania, the subject matter has been modified so as to deal with preventable diseases. The foundation has been laid in authorities considered most trustworthy in the various departments, and the views of many are often given without the author committing himself definitely. Frequent requests coming to the writer for the details of management of transmissible disease have prompted him in the preparation of this work, and the reader will often find answered just the kind of questions he would himself have propounded. Many useful suggestions concerning the care of the patient's surroundings, bed, room, clothing, excreta, attendants, etc., will be found. Formalin diluted with glycerin and used in a generator is preferred for room disinfection. The subject of hygiene, especially in the present connection, is of vast importance, and such a work as that now presented should find many readers.

Asthma: Recent Developments in its Treatment. By Ernest Kingscote, M.B., C.M., L.R.C.S. Edin., Author of "So-Called Spasmodic Asthma." With colored frontispiece and illustrations. London: Henry J. Glaisher. 1899.

This is in many respects an interesting work, in that recent views are brought forward, and, in a subject to which the author has evidently devoted much attention, he is enabled to give valuable personal experience concerning the conditions of the heart found in this class of patients. The Schott treatment is highly thought of, and the author finds that bringing back the heart to its normal size is of the greatest benefit. Vagal implication and irritation, vagal pressure, vagal autotoxic neuritis have all been discussed. The actual study of asthma proper begins at Chapter XII., on page 89. There are in all one hundred and sixty-eight pages of text. Many theories will be found advanced with which perhaps the reader cannot at once agree, but the work should stimulate to further observation and study.

Diseases of Children. By C. Sigmund Raue, M.D., Visiting Physician to Children's Homœopathic Hospital and Chief of Children's Clinic, Philadelphia; Visiting Physician to Children's Wards in the Woman's Homœopathic Hospital, Philadelphia, etc. Philadelphia: Boericke & Tafel. 1899.

This is a work based upon personal clinical experience, observation, and the results of treatment as studied at the bedside. Including the index, there are four hundred and seventy-three pages in which the various ailments of infancy and childhood are depicted. The commoner forms of skin diseases occupy a separate chapter, written by Dr. Ashcroft, who is lecturer on venereal diseases in the Hahnemann College of Philadelphia. The chief distinction made is between diseases due to external irritants and those depending upon the "psoric taint." Vaccination is looked upon as playing a rôle in the causation of eczema, and parasitism is considered largely responsible for the pustular form, especially that of the scalp. The differentiation from syphilis is inadequate. While it is claimed that eczema is due largely to the existence of a psoric taint and can be successfully eradicated only by the administration of a well-selected internal remedy (graphites, rhus, hepar, sulphur, etc.), still the usual list of external remedies—including ichthyol, which is highly spoken of—is given, and we are told that the external exciting irritant must be removed. Ecthyma is considered a disease of adult life only. Fisher's prescription for scabies calls for sulphur and balsam of Peru, each ʒ iiij. (*sic*); lard and vaseline, each ʒ ss.—which looks very much like equal parts of all. Dr. Bayley, lecturer on mental and nervous diseases in the college, is given credit for suggestions in the chapter on diseases of the nervous system. The indication of the remedy without definite direction as to dose to meet the varying conditions and ages, would seem to constitute a weak feature of the work.

Pocketbook of Medical Practice, Including Diseases of the Kidneys, Skin, Nerves, Eye, Ear, Nose and Throat, Obstetrics, Gynæcology, and Surgery. By Ch. Gatchell, M.D., Editor of *Medical Era*, Professor of Diseases of the Chest and Physical Diagnosis in the Chicago Homœopathic Medical College. Chicago: Era Publishing Company. 1899.

This is a small, neatly bound volume, similar to several pocket formularies on the market. The therapeutic part, dealing as it does with homœopathic drugs and doses, contains no formulæ, which is the chief feature of the little works recently put out by several publishing houses. The local treatment is almost wholly founded on old-school lines. Though several chapters have been especially prepared by those identified with the particular branch, much is left to be desired in the description and diagnosis of many diseases. The paper is too thin, allowing the print to show through. An appendix contains bacteriology, diet, baths, poisons, antidotes, etc.

Progressive Medicine. Vol. III. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Octavo, handsomely bound in cloth. 440 pages, 11 illustrations. Philadelphia and New York: Lea Brothers & Co.

The contributors to the third volume of this year book are William Ewart, Richard Norris, William Spiller, and Henry Stelwagon. The first discusses the diseases of the thorax and its viscera, the second covers the field of obstetrics, Spiller treats of diseases of the nervous system, and Stelwagon of those of the skin. The editors of the different departments have done their work in a conscientious manner, and, while not taking in all that might be considered "progressive," they have not encumbered the pages with much that is already known by text-book readers and students in general. The majority of the references are to journals of 1898, and those who have kept abreast of the time in any particular branch by reading weeklies and monthlies may find little which will be actually new to them. Unless, however, they have prodigious memories, they will take both profit and pleasure in going again over the ground in company with such able abstractors and commentators as have had these four subjects in hand.

Thérapeutique Obstétrical. Par le Docteur A. Auvard. Deuxième édition. Avec 129 figures dans le texte. Pages 331. Paris: Octave Doin. 1899.

The flexible morocco covers of this little volume prepared for students' use and handy reference make it very attractive, and remind an American of the celebrated Baxter's Bible, so much carried about by Sunday-school teachers and like godly-minded folk. The illustrations are very well executed, and are clear and practical. The book forms one of a series of which there are to be forty volumes, which deal with medical and surgical therapeutics. The work contains much besides the actual treatment of obstetrical conditions, since it is necessary for the complete understanding of the subject. Instruction for Americans from the French point of view in the matter of obstetrics might be thought to be bringing coal to Newcastle, but the student and physician will see matters with French eyes in reading the work, and will get ideas which will enlarge those already possessed and suggest new trains of thought.

# Society Reports.

## THE NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, October 11, 1899.*

T. Mitchell Prudden, M.D., President.

**Carcinoma Gelatinosum Mammæ (Carcinoma Mucosum).**—Dr. E. Hodenpyl presented this specimen. He said that it was of comparatively rare occurrence, and when the specimen first came into his possession he imagined it might be almost unique, at least so far as the situation of the lesion was concerned. He had found, however, in Ziegler's "Pathology" a very good short description of gelatinous carcinomata of the breast, with a drawing of a case similar to his own; and in Bruns' *Beiträge*, 1896, vol. xvi., he had found an elaborate monograph on this subject by Dr. Fritz Lange. The latter contained a *résumé* of all the recorded cases, seventy-five in number. Roger Williams, in his new text-book on "Tumors of the Breast," had stated that, although the disease had been described, he had never met with a case. The patient from whom this tumor had been removed was admitted into Roosevelt Hospital, on account of a tumor in the left breast. She stated that it had been there "as far back as she could remember." For many years it had been about the size of an egg, was hard and painless, and showed little if any tendency to increase in size. A year and a half before its removal the mass had been struck a severe blow, in a fall, and after this it had increased in size. About three months before coming under observation she had accidentally struck the breast again. Shortly after this an opening formed near the nipple, from which dark bloody fluid had escaped. Since this second traumatism the increase in growth had been quite perceptible, and the breast had become tender. Examination had shown a tumor, about four inches in diameter, which was unusually hard. The mass was freely movable, and apparently not adherent to the pectoral muscle. No axillary lymph nodes were palpable; there were no disturbances of sensation in the left arm; there was no cancerous cachexia. The patient stated that she had recently lost some flesh and strength. When Dr. McBurney first saw the case, he was in some doubt as to its nature, and had accordingly requested the speaker to make a preliminary microscopical examination at the time of operation. The examination was, in this case, particularly puzzling, for the reason that the mass submitted and removed from the densest portion of the tumor resembled a quantity of jelly-like substance. On section, it presented a general alveolar arrangement of the connective tissue, the spaces of which were filled with a homogeneous, transparent, jelly-like substance. He concluded that the tumor was a carcinoma which had undergone extensive degeneration. The entire breast, including the axillary contents and pectoral muscle, was removed, and the patient made a satisfactory recovery. The tumor, which was exhibited, was hardened in formalin. It had to a great extent replaced the mammary gland, and consisted largely of a soft, jelly-like substance. In places there were old hemorrhagic extravasations. It was partially encapsulated and contained some calcareous patches. There was a single enlarged lymph node between the tumor and the pectoral muscle, and two or three very small axillary nodes had been dissected out. In the microscopical examination made by Dr. Hodenpyl he had found nothing in the central portion other than alveolar arrangement, the spaces being filled up with a gelatinous material. It was only near the periphery that one could find the usual evidences of carcinoma—alveoli filled with epithelial cells. The lymph nodes were not involved. In all of the sections of the tumor, as well as the lymph nodes at a distance from the tumor, the blood-vessels contained numerous rather large and intensely black granules. Some of these granules were also scattered about in the tissues. The nature of these granules of pigment was afterward explained, when it was learned that the wound made in removing the specimen for microscopic diagnosis had been treated with the actual cautery to control hemorrhage. Dr. Hodenpyl said that, according to Lange, this gelatinous type was very much less malignant than the ordinary form of cancer of the breast. In many of the reported cases the tumor had existed for from six to eight years, and, in one instance, for twenty-three years before removal. As a rule, the tumors had not been larger than a walnut. Occasionally they reached the size of an egg. Ordinarily there had been no lymph-node enlargement. Calcareous degeneration was quite a common feature. Metastases had not been very common. Out of twelve recorded autopsies of individuals who died after removal of gelatinous cancers of the breast, metastases had been found in only five cases, and these had been most often present in the lungs or in the liver. Local recurrence had not been a frequent feature. Three of the cases had been peculiarly interesting, in that the individuals had carcinoma of both breasts. In one case the carcinoma on one side was gelatinous, and on the other side it was of the ordinary scirrhus variety. In another case the gelatinous form had complicated a Paget's carcinoma of the opposite breast. In still another, the carcinoma had been gelatinous on both sides. One instance had been reported in which it had occurred in the breast of a male. Lange had thrown no additional light upon the chemical nature of this peculiar substance. Johannes Müller had examined chemically a number of these cases without finding any mucin in them, but other observers were quoted who claimed to have found mucin. With regard to the source of origin of the gelatinous substance, Lange, agreeing with other observers, believed that, unlike the ordinary form of so-called "colloid carcinoma" of the stomach, it did not originate within the epithelial cells of the tumor. The jelly-like substance, as it increased in amount, caused a secondary atrophy and more or less total obliteration of the epithelium. This statement seemed to be borne out by sections from the speaker's case. It appeared probable that the gelatinous material had its origin in the connective-tissue elements of the growth, but more investigation was needed to clear up this point.

**Carcinoma Gelatinosum of the Stomach—Carcinoma Gelatinosum of the Lung.**—Dr. J. H. Larkin presented these two specimens of carcinoma gelatinosum in connection with the preceding. The first specimen was one of carcinoma gelatinosum of the stomach which had been removed from a man fifty-four years of age, who had given a history pointing to carcinoma, dating back six or seven months. The tumor in question occupied the anterior and posterior walls of the stomach, extending from the cardia to the pyloric end, along the lesser curvature, the only portion of the stomach not involved being the greater curvature at the pendent portion. The thickness of the stomach wall involved by carcinoma was about one to one and a half inches, the portion not involved being greatly thinned out. The pylorus was almost entirely occluded. The inner wall of the stomach over the infiltrating mass was changed into a trembling jelly. The peritoneum over the greater curvature was glistening and shining, while that over the tumor was lost and studded with myriads of tiny gelatinous masses. These small jelly-like bodies were also present on the mesen-

tery and the under surface of the diaphragm. There were no metastases in the other viscera. The noteworthy features of this specimen were the abrupt stoppage between the carcinoma and the more normal stomach wall at the greater curvature, the great thickness of the stomach wall and the direct extension of the infiltration through it, and the appearance of myriads of gelatinous masses in the mesentery.

Dr. Larkin also exhibited a gelatinous carcinoma originating primarily in the peritoneum. It had been taken from a woman, aged sixty-five years, who had not given any history of previous illness. She had died of chronic Bright's disease. At the autopsy myriads of small gelatinous masses under the pleura and in the substance of the lung were discovered. A thorough search had been made in the peritoneum, and alongside of the cœliac axis a small mass, about three-quarters of an inch in diameter, had been found. This had been removed, and it had then been found that the mesenteric glands back of the mass were enlarged and gelatinous. On microscopical examination of the tumor in the peritoneum it was found to be made up of irregular connective-tissue spaces lined with high cylindrical epithelium. The cavity was filled with gelatinous material, staining with hæmatoxylin, containing a few cells. The same appearance was presented in a node found on the superior surface of the liver. The small gelatinous metastases in the lung had presented the same irregular network of connective tissue made up of the connective tissue of the old walls of the air vesicles. The characteristics of the other tumors were still preserved. In the masses in the lung the mucous material was very abundant. The speaker asked for information regarding the proper classification of tumors of this kind.

Dr. P. A. Levene said that even mucin had not been studied very much by the physiological chemists. It had been considered to be a proteid combined with sugar. If considered to be a glucoside, one could not explain its pathological origin as a product of decomposition. If mucin was a proteid molecule having in it a carbohydrate, one would be inclined at the present day to look upon this material as a product of the function of the cell rather than of its decomposition. He was at present working on one of the mucins, and as far as he had gone he had been led to look upon it as a product of decomposition. He thought mucin consisted of two parts, one part being the product of metabolism—an acid which subsequently combined with a proteid.

Dr. Ernest E. Smith thought a good deal of confusion existed among chemists as well as among pathologists as to what mucin was, because they had attempted to include in the class of mucins all mucilaginous substances in the body. At one time he had undertaken a study of the mucous material of the alimentary tract, and had found that it was not mucin. He did not believe that the slimy material in the bladder was mucin at all. The mucous material of the intestine did not at all conform to the rather dogmatic requirements of chemists for this class of bodies, viz., that it should be composed of carbon, hydrogen, sulphur, nitrogen, and oxygen and that it should give a reducing substance when boiled with acids. Of course, true mucin was found in saliva and human bile. The other class of mucilaginous substances seemed to be more closely allied to the nucleoproteids Bladder and intestinal mucus, in his opinion, were of this latter class. He thought it probable that the gelatinous substances which were the result of decomposition or degeneration were allied to this class rather than to true mucin.

Dr. Levene said that Swedish investigators had shown that the mucin of the bile was not a true mucin, but a nucleoproteid. The trouble had been that formerly every proteid that gave a reduction test was considered a mucin, but it was now known that all the nucleoproteids contained a carbohydrate molecule. In his opinion, all the nuclein forms could be distinguished from mucin histologically by their behavior with staining agents.

Dr. Smith added that since the first statement had been made, that the mucous substance of the bile was a nucleoproteid and not mucin, the substance occurring in human bile had been investigated, and it had been found that mucin did occur in human bile. The original substance investigated had been ox bile, and this did contain nucleoproteid, and not mucin. The fact that nucleoproteids yielded a reducing substance when boiled with acid was no reason for confusing these compounds with true mucins, since, as already said, mucins contained only carbon, hydrogen, sulphur, nitrogen, and oxygen, while the nucleoproteids contained phosphorus in addition to these.

Dr. Prudden said that he did not know why in this country we were calling these tumors "colloid," as they did not contain the substance giving the chemical reactions of colloid as it was found in the thyroid gland. Germans called them "gelatinous," and this seemed to be a more appropriate term. There was a large group of hyaline materials appearing under a variety of pathological conditions in the body, and which, with our present knowledge, could not be definitely separated one from the other. It was perhaps wise, under these circumstances, to consider them as a group of hyaline substances which were yet to be differentiated by the chemists, and to which we should attach special names as the result of superficial microchemical tests only with considerable reserve. The metastases in the lung of Dr. Larkin's gelatinous carcinoma seemed especially interesting because in places, instead of forming its own stroma as it grew, it had made use of the walls of the air vesicles, so that in places these vesicular walls, recognizable by their capillaries, by pigment, and by form, were to be seen lined with cuboidal and cylindrical epithelium and filled with gelatinous substance. Under ordinary circumstances in the growth of a carcinoma, the increase in stroma and in epithelium went hand-in-hand, and one might well be in doubt which took the initiative. But here, the epithelial cells, having an appropriate base, seemed to have gone ahead on their own account. Thus these metastases, in addition to their intrinsic importance, seemed to afford a half-glimpse into that border-land of cell impulse toward which attention was so generally turning to-day.

**Tumor of the Nymphæ.**—Dr. Larkin presented for Dr. Matthews a large tumor that had been removed from the nymphæ of a negress, twenty-four years of age, who had given a definite history of syphilis, and of this growth having existed for one year. Microscopically the tumor was made up of œdematous connective tissue containing numerous blood vessels surrounded, for the most part, by small lymphoid cells. The question arose as to whether syphilis had anything to do with the tumor. Personally he did not think it had.

**Two Cases of Absence of One Kidney Associated with Presence of a Double Uterus.**—Dr. Leon T. Le Wald presented these cases. He said that while he had met with these two cases within a few days of each other, a search of the literature had confirmed his former opinion that they must be extremely rare. The left kidney had been absent in both instances. The first patient, a woman of forty-seven years, had died of an acute lobar pneumonia. There was only one ureteral opening in the bladder, and no trace of a ureter or kidney could be found on the left side. The kidney was double the normal size and weight. The internal genital organs showed a malformation in

the shape of a distinctly double uterus of the type known as "uterus bicornis." In the second case, that of a woman aged thirty-two years, there had been a pyonephrosis and a perinephritic abscess. An incision had been made into the abscess and into the substance of the organ. So far as known, no cystoscopic examination had been made, hence if the operation had been pushed further the only kidney present might easily have been extirpated. In this case there was also present a double uterus, but of a different type from the first case. Externally the uterus departed from the normal only in the appearance of a slight depression at the middle of the fundus, but internally it presented two distinct cavities opening into a single cervix—"uterus bilocularis." The absence of the left kidney was believed to be more common than that of the right. The relation between this anomaly and the occurrence of double uterus had not been determined.

Dr. Larkin said that he had met with two cases of absence of the kidney—in one it was the left, and in the other the right kidney that was missing. In one of these cases there had also been an adenoma of the kidney.

**Diverticulum of the Bladder.**—Dr. A. V. Moschcowitz presented this specimen that had been taken from a man seventy-three years of age, who had been admitted to the surgical ward of the Mount Sinai Hospital with the presumptive diagnosis of specific urethritis. The speaker had examined the patient at the time of his admission, and had found the body temperature to be 103.4° F. and the pulse 140. The patient stated that he had noted no special difficulty with urination up to one week previously, at which time there had been acute retention. Repeated but nearly futile attempts at catheterization had been made before coming to the hospital. The skin covering the dorsum of the glans penis was black and necrotic; there was a fetid purulent discharge from the urethra. There was a hard swelling a little back of the meatus. A diagnosis of impacted calculus in the urethra had been made, and after irrigation a calculus had been easily removed with the aid of forceps. A catheter of large size, and even a Thompson searcher, could then be introduced into the bladder without difficulty. The urethra and the bladder were freely irrigated, but there was nevertheless a continuous discharge of blood and pus, and the patient was badly septic. One week later suprapubic cystotomy was accordingly performed, and with the patient in the Trendelenburg position three calculi were removed. He had been surprised to note that at each inspiration, instead of at much longer intervals, there had been a jet of urine from one of the ureters. Closer inspection showed the opening to be not the ureter, but a diverticulum of the bladder filled with stones; these were removed. The patient had died of septicæmia the following day. Only a partial autopsy had been permitted. One ureter, instead of being in the natural place, was situated on the anterior portion of a diverticulum of the bladder. There were forty calculi in the diverticulum and three in the bladder proper.

**Tuberculosis of the Genital Tract.**—Dr. Moschcowitz also presented specimens from a case of tuberculosis of the genital tract. They had been taken from a man who had been admitted to the Mount Sinai Hospital with a swelling of the left epididymis. Nothing abnormal was felt in the spermatic cord or vas deferens. On rectal examination the corresponding seminal vesicle presented a nipple-like projection into the rectum. The case was considered an ideal one for a radical operation. Accordingly, an incision had been made along the scrotum and the testicle everted. The entire epididymis had then been dissected off without injury to the testicle. While the spermatic artery was compressed the testicle was inspected. As much of the vas deferens as possible was pulled out and a catgut ligature applied to the stump as a guide; then, the patient having been placed in the lithotomy position, a curved incision had been made around the anus, extending from one tuberosity to the other, and then by blunt dissection he had been able to reach up to and beyond the prostate. The seminal vesicle was then extirpated, being cut off as closely as possible to the ejaculatory duct. He had then taken hold of the stump and withdrawn the remainder of the vas deferens. It was now two months since the operation, and there had been no complication and no evidence of tuberculosis in the genital tract. The enlarged epididymis and the other organs, examined by Dr. Mandlebaum, pathologist to the hospital, showed numerous tuberculous abscesses and cheesy deposits. There was pus throughout the vas deferens and in the seminal vesicle.

**Changed Appearance of Diphtheria Bacillus.**—Dr. W. H. Park said that in having a photograph made recently of a diphtheria bacillus that had been under constant cultivation for four years, he had been struck with the change in its appearance. It was now twice as long as before and more slender, and did not present the appearance of the diphtheria bacillus, while before it was very characteristic in its clubbed forms.

**Antitoxic Globulins.**—Dr. Park, on behalf of Mr. James P. Atkinson, the assistant chemist in the research laboratory of the New York health department, presented a communication on the subject of antitoxic globulins. He stated that for two years past Mr. Atkinson had been testing the globulin in the antitoxin horses. He had thus found that the globulins increased as the antitoxin in the blood increased. It had been found that the globulin of normal horse serum and diphtheritic antitoxic horse serum, after separation from the serum by means of magnesium sulphate, might be separated into five fractions by the following method: The watery globulin solution was saturated with sodium chloride. This yielded a precipitate at the normal temperature. After filtering off this precipitate, a little more sodium chloride was added to the filtrate to insure saturation, and the temperature raised to 40° C. A turbidity appeared which, on raising the temperature higher, separated out in flocculi. At 45° C. the precipitate could be filtered off. At 49° C. the third precipitate commenced to come down, and at 53° C. it might be filtered off. The fourth precipitate came down between 57° and 62° C., and the fifth precipitate came out between 67° and 72° C. These precipitates were almost completely soluble in water. The 67–72° precipitate left a slight residue in water, but was soluble in dilute soda solution. An interesting feature of this process was that each one of these precipitates was antitoxic, and that the total globulin of the blood appeared to contain all the antitoxin, the moderate amount lost in the final precipitates being due, it is believed, to the effect of the heat used. Dr. Park added that they were going to give the antitoxic globulins to children instead of the antitoxic horse serum, to see if the rashes could not in that way be eliminated. By experimenting with these five globulins it was thought not improbable that more light could be obtained on this subject.

Dr. P. A. Levene said that it would be interesting to know if these different globulin precipitates varied in their physical characteristics. He was reminded of the experiments made at one time on Koch's tuberculin by Professor Kuhne. The conclusion had been reached in these experiments, that the toxin of the tuberculin was not chemically combined with these albumoses, but was merely carried down mechanically. The more flocculent the precipitate the more likely

was it to carry down the antitoxin mechanically. As to the increase of globulins in antitoxic horses he was not sure that the increase of the globulin was due entirely to the abnormal condition of the horse. In a study of artificial diabetes that he had made he had found that the quantity of globulin had increased as a result of the pathological state which existed.

Dr. Park replied that the horses which yielded the most antitoxin and seemed to be in the best condition yielded the most globulin. So far as he had observed, all these five globulins looked alike. As long as there was some globulin left in the serum from immunized horses, there was some antitoxin. No globulin from antitoxin serum could be extracted that was not, at least, feebly antitoxic.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, November 2, 1899.*

William H. Thomson, M.D., President.

**The Pathology of Lobar Pneumonia as a Basis for Treatment.**—Dr. Andrew H. Smith read a paper on this subject. In using the term "pneumonia" he said that he desired to restrict it to the form variously designated as lobar, fibrinous, or croupous, the form which, in typical cases, was ushered in abruptly by chill and fever, and which, after from four to nine days, if the patient was to recover, ended suddenly by crisis. Pneumonia, he said, was not an inflammation of the lung, although pneumonitis could be produced at will in one of a great many ways. Inflammation, suppuration, and even gangrene might be produced, but it would not be pneumonia. There was one thing which introduced into the parenchyma of the lung would always produce pneumonia, and that was the pneumococcus. These facts served to differentiate sharply between pulmonary inflammation and pneumonia. It was not enough to admit the infectious nature of the disease and define pneumonia as an inflammation excited by the presence of a specific parasite. The parasite was unquestionably there, but it did not excite an inflammation. In pneumonia the parenchyma of the lung did not suffer; at most there was a certain amount of desquamation of the epithelium. There was nothing left to represent the results of inflammation. The tremendously active process that had gone on in the lung vanished, and left no trace behind it. For this we had to thank the special nutrient circulation provided by nature. At the same time, and in the same area, one could see the action of the right heart completely suspended, and that of the left heart going on actively. In the pneumonic lung, the capillaries which were the continuations of the pulmonary artery were completely thrombosed, and this thrombosis extended back to the heart. If the entire lung were involved the thrombosis would extend back into the bifurcation of the pulmonary artery. The blood supply from the bronchial arteries, on the other hand, was completely free from obstruction. In pneumonia we had to deal with a process of germ culture going on in a culture medium, each air cell acting as a tiny test tube, and filled with this culture medium. The complicated manifestations completing the clinical picture of pneumonia were epiphenomena. Two of these epiphenomena were of extreme importance, constituting singly, or together, the chief menace of life, viz.: (1) Infection of the system by toxin formed in the lung, and (2) the embarrassment of the lungs from the exudation in the air cells. From the first arose a host of manifestations dependent upon toxæmia; from the second, we had the ever-present danger of failure of the right heart.

**Treatment.**—Heretofore the treatment of pneumonia had been far from satisfactory, pneumonia destroying more lives than any two other acute diseases put together. Within the past decade, however, there had seemed to be the dawning of a better era. The problem before us was first of all to arrest or inhibit the growth of the pneumococcus, bearing in mind the peculiarities of the organ in which the disease process took place. It should be remembered that the life of the organism was short, not exceeding ten or twelve days in artificial cultures. Another interesting fact was, that this was one of the most sensitive of all germs, its growth being arrested by very slight changes in its surroundings. If we could impregnate the blood sufficiently with a substance inimical to the growth of the pneumococcus, there would be a chance of forestalling the local process. The local process was always a spreading one, so that it seemed perfectly feasible to prevent the spread of it to other cells than those first invaded. Long before the microbic theory of pneumonia had been understood, or even thought of, calomel had been a favorite remedy, although given with the idea that it was an antiplastic. The older practitioners rarely had the hardihood to treat a case of pneumonia without a mercurial. In 1878 Dr. Mary Putnam Jacobi had reported the result of an investigation into the action of the so-called "sedative dose" of calomel in pneumonia. The results from this treatment, which had been a favorite one with the late Dr. Leaming, had been quite remarkable. Quinine, though a feeble antagonist to other than malarial germs, was known to have a decidedly beneficial action in pneumonia when given in rather large doses. This was not surprising when one considered how thoroughly this remedy pervaded the whole system. Dr. J. S. Thacher, at his suggestion, had made a number of experiments in the laboratory of the Presbyterian Hospital, regarding the effect of chloroform on the pneumococcus, and these had abundantly substantiated what had long been known from clinical observation concerning its powerful influence in pneumonia. Creosote had been highly lauded by a number of observers as a useful remedy in pneumonia. It had been given by the mouth and in enemas. The carbonate of creosote had been found to saturate the blood readily without irritating the stomach, and without giving rise to poisonous or other untoward effects. A very remarkable series of seventy-two cases of pneumonia occurring in Austria among miners had been reported. All of these had been treated with large doses of sodium salicylate—gr. cxx. daily. All of these patients had recovered, and in not one had the disease terminated by crisis.

**A Possible Prophylactic Treatment.**—The treatment should be instituted, in all cases of pneumonia, at the earliest possible moment. The occurrence of the chill was a certain indication that a considerable amount of toxin had been already formed in the lung and had been taken into the general circulation. As the disease progressed, one after the other of the air cells would shut off, and in each one of these the germ culture must be allowed to go on. The young, newly formed cocci were the most virulent, as had been proved by laboratory cultures, and it was in the half-filled cells in which the blood was still flowing that these cocci were present in large numbers, and hence it was never too late to begin treatment. Dr. Smith said that, in his opinion, the family physician should instruct his patients to keep in stock some preparation of creosote or a salicylate, and to begin its use immediately upon the first sign of chill or pain in the chest. By this means he believed pneumonias might, in many instances, be prevented from developing. His experience with this comparatively new treatment had been rather limited, but so far it had been encour-

aging. At one time he had thought well of the salicylates, but was now inclined to believe that, in the later stages, they were depressing, and certainly they were always irritating to the stomach. He now preferred creosôte carbonate, also known as creosotal.

**Accessory Treatment.**—The accessory treatment embraces: (1) Stimulation of the emunctories to carry off the poison; (2) sustaining the heart by the use of cardiac stimulants; (3) the use of vasodilators or of venesection; (4) compensation for the loss of respiratory surface by inhalations of oxygen; (5) reduction of the temperature, as by the application of cold to the surface, and (6) relief of the incidental symptoms. When the chief danger to life was mechanical, from obstruction to the circulation, as shown by the labored respiration and the presence of cyanosis, he would give nitroglycerin, and not digitalis. If the patient's face could be kept florid, there might be hope, but blue lips were the shadow of death. He infinitely preferred the big pulse, however soft or gaseous, to a tiny thread which the finger could scarcely discover. Under these conditions he had never known the pulse to become full and slower from the administration of digitalis. Regarding the so-called digitalis treatment the speaker said that the infusion of digitalis used by Putresco did not represent the drug, containing chiefly digitalin and digitonin, and he would hazard the opinion that the good effects obtained from such administrations had been rather from the action on the heart than on the pneumococci.

**Not Very Hopeful.**—Dr. Frank W. Jackson thought it must be admitted that as yet we had no specific for pneumonia. There were almost as many different methods of treatment as there were prominent men in medicine, and so far as he could see the results were about the same with each. The subject, therefore, seemed to narrow itself down to the matter of individual treatment. Having studied under Dr. Leaming he had, at one time, had a large experience with the calomel treatment, giving gr. xxx. as early as possible, and repeating this, or a larger dose, in a few hours. He was free to say that he had never injured the patient, and had observed the beautiful sedative and antipyretic action of this medication, but unfortunately the fever and other symptoms would return within twelve hours or more, and the case would apparently progress just as if the calomel had not been given. In recent years he had scarcely used this treatment at all, although it must be admitted that even salivation had been exceedingly rare with it. When an interne in the Roosevelt Hospital, the routine treatment had been the administration of large doses of quinine and the application of an oil-silk jacket. At that time he could not see that any good results followed this use of quinine. He had used creosotal in a few cases of pneumonia, and it had not seemed to him to have much effect. He did not have much faith in creosote as a germicide for disease of the lung, and this opinion was founded on a considerable experience with it in tuberculous patients. He had seen many pneumonias, under active treatment, recover in thirty-six hours, and, again, he had seen them recover in twenty-four hours without any treatment. Just here was the stumbling-block in drawing deductions from the use of drugs, or the adoption of special modes of treatment. There were, indeed, many cases in which the physician was not called upon to institute any special treatment; in others, opium might be most beneficially employed. He would pin his faith on the serum treatment of the future as apparently the most rational method.

**Fascinated but Not Convinced.**—Dr. Alfred Meyer emphasized the importance of individualizing the treatment, not only in pneumonia, but in many other diseases. The idea that pneumonia was a non-inflammatory disease had been presented by the author of the paper in a most fascinating manner, yet he cautioned those who had heard it not to be fascinated to such an extent as to prevent their reason from having proper sway. The fact that the same micrococci might excite inflammation in other regions of the body, as, for example, in the serous cavities, was, at least, very significant. The anatomical picture of an inflammation always varied according to the structure involved, and whether or not the process was acute or chronic. He would raise the question, in this connection: Is erysipelas of the face any the less an inflammation because the result of micro-organisms than the dermatitis produced by exposure to the sun? Moreover, microscopical evidence was not wanting to show that the epithelium of the air cells actively participated in the process. There seemed to be more hope from the salicylate treatment than from any other thus far presented. One should be very cautious in making deductions from statistics of any method of treatment because of the varying type of the disease. Thus, in a recent study that he had made of five hundred cases of lobar pneumonia occurring in the Mount Sinai Hospital during a period of ten years, the mortality had varied from eight per cent. in 1897 to twenty-nine per cent. in 1898.

**Pneumonia in Children.**—Dr. H. D. Chapin spoke of the disease as found in children. He called attention to the fact that the right heart of the child was usually very strong, and hence little trouble was experienced on that score. He had tried creosote, but without specially good results. He had employed both medicated and unmedicated steam, and had been pleased with the effect, which, however, had seemed to him to be equally good from the steam alone. Since Dr. Smith's earnest advocacy of nitroglycerin in pneumonia he had used it extensively, and with much success. In regard to the germicide treatment he would only say that all of these remedies were depressing. He would not like to treat the pneumonias which he saw with large doses of either calomel or the salicylates. In septic pneumonias one would look for the best results from such remedies, yet he thought he would be a bold physician who would make use of large doses of drugs of this class in these cases. While deeply interested in the paper, he had not been convinced, and probably would not be until a very large series of cases had been presented, together with minute details regarding the type of the disease and the influence of individuality.

**Pneumonia a True Inflammation.**—Dr. E. K. Dunham said that year after year he had made use of pneumonia, in his teaching, as a typical example of inflammation, and he utterly failed, from his microscopical studies, to see anything which would enable him to separate acute lobar pneumonia from other recognized inflammations. The same process that was observed in lobar pneumonia was also seen around tubercles or hemorrhagic infarctions in the lung—at least the microscope failed to show any difference. From sections of pneumonic lung which he had examined, it seemed to him that not only did the exudate show the process to be an inflammation, but also the reaction on the alveolar wall seemed to be indicative of an inflammatory process. Dr. Dunham then exhibited under the microscope the following specimens: (1) A section of the brain and pia mater from a case of fibrino-purulent leptomeningitis; (2) a section from a case of croupous pneumonia; (3) the alveolar wall in another section of the same lung, showing the increased tissue and thickening of the alveolar wall and what he took to be a rejuvenescence of the cells; (4) a section of alveolar wall of a lung the seat of simple œdema, showing no reproduction of tissue, and (5) a section of the same lung which had been stained for

the micro-organisms present, and showing what appeared, from their morphology, to be typical pneumococci. It did not seem to him necessary to regard pneumonia as anything but an inflammation in order that the arguments presented for treatment need hold, nor did he think it necessary to divide the circulation of the lung in the manner that had been done by the reader of the paper. If the nutritive supply was so excellent, he saw no reason why the parenchyma of the lung should die after hemorrhagic infarction. That the vessels should be found filled with fibrin after death was not remarkable because of the condition being so favorable to coagulation.

Dr. James K. Crook said he did not see but that Dr. Smith admitted the existence of all the recognized essentials to a true inflammatory process. Many mild inflammations resolved without leaving any structural alteration. In many severe cases of pneumonia there was certainly interference with the bronchial circulation, and in many fatal cases the autopsy would show the involvement of the entire structure of the lung by the presence of suppuration or of gangrene. Although not agreeing with Dr. Smith on these points, he felt disposed to accept his theory of the cause of the defervescence. Regarding the proposition so to change the composition of the blood that the exudate poured out from it into the air cells might prove inimical to the pneumococci, Dr. Crook said that at the very outset one was met with the fact that pneumonia was often apparently the result of a mixed infection. While, therefore, it might be perfectly feasible to check the growth of the sensitive pneumococci, the matter was quite different when other and more resistant germs were partly responsible for the disease process.

**Abortive Treatment not a Myth.**—Dr. Edward H. M. Sell said that, looking back thirty years, the view was very interesting. About thirty years ago this very subject had been discussed in the Medical Society of the County of New York, and very nearly the same diversity of opinion had existed then. At that time the application of ice to the chest had been suggested, but the treatment had been very quickly abandoned. In those early days he had had the audacity at one meeting to speak of the "abortive treatment" of pneumonia, and had been severely criticised because of his belief in such a possibility. It would seem that this was just as much questioned at the present time. Dr. Sell then referred to a severe case in which, by the use of small doses of tincture of aconite and the application of the very old-fashioned poultice, he had caused a subsidence of all the symptoms within twenty-four hours.

**Pneumonia and Typhoid Contrasted.**—Dr. William H. Thomson referred to the contrast between two important infections—typhoid fever and pneumonia. In both the patients usually died of a toxæmia; in both there would be observed marked variations in the type of the disease in different years. But here the similarity ended. Typhoid fever began very insidiously, and progressed slowly, and subsided gradually. Pneumonia, on the other hand, began abruptly, developed rapidly, and was the only disease among the entire class of infections which ceased suddenly. Despite some recently expressed opinions to the effect that there had been no difference in the mortality of typhoid fever from any method of treatment within the past thirty-five years, he had no doubt that the long course of typhoid fever did allow physicians materially to modify that disease. Only last week he had stated in this hall that out of three hundred and forty-four typhoid patients who had been more than one week in his ward in the Roosevelt Hospital, the mortality had been only three per cent., and if these cases had been under treatment from the very beginning, he felt that the mortality might have been reduced to one or two per cent. There was no disease that he felt more pleasure in treating than typhoid, because of the comparative certainty he felt of securing a good result. On the other hand, he felt apprehensive when called upon to treat a pneumonia because he was impressed with the essentially toxic nature of this disease. An important step in advance had been made when the profession had been asked to abandon the old idea that pneumonia was a pneumonitis. Every clinician knew that the gravity of the symptoms bore no constant relation to the amount of lung involvement. He challenged any one to name another disease, and particularly a serious inflammation, in which there was such a sudden termination by crisis as in pneumonia. This meant really an abrupt termination of the toxæmia. A case of pneumonia was really a case of poisoning, and what could be more unsatisfactory than treating such a case by the indications arising from the disturbed functions?

**New Treatment for Pneumonia Demanded.**—He did not believe the mortality from pneumonia in hospital practice had varied at all during the thirty-six years of his experience. We should, therefore, look in an entirely different direction for an advance in the treatment—most probably in the direction of an antitoxin. Theoretically speaking, pneumonia would appear to be the disease for which an antitoxin ought to be discovered. Notwithstanding the failures of many observers in the past, he believed that it would be found, but he would expect that such an antitoxin would have to be used very early in the disease, and in very large doses, and that considerable difficulty would be experienced in manufacturing an article having much stability. Another direction in which we should look had been suggested by the paper of the evening—a mode of medication which would check the growth of the pneumococci.

**The Chloroform Treatment.**—He had been occasionally called in to see cases in which there had just been a violent chill, followed by bloody sputum, and had succeeded by the administration of about ♏ xxx. of chloroform in preventing the development of other symptoms. At one time he had treated ten pneumonias in alcoholic subjects, and every one of them had recovered, but having subsequently had one or two patients die very suddenly after the reduction of the temperature, he had abandoned this treatment. He was inclined to think that such medicinal germicides were dangerous. The fact that the pneumococcus could both lose virulence and gain virulence explained many recoveries and relapses. This fact also gave some hope that, from its sensitiveness in the laboratory to certain substances—notably chloroform and carbolic acid—better therapeutic results might be attained along the lines laid down in the paper by Dr. Smith. In one exceedingly unfavorable case of double pneumonia he had given twenty grains of carbonate of creosote, in emulsion, every two hours, and no other medication whatever. The man had recovered, but the disease had not terminated by crisis. A second case was that of a colored man who had been brought in with high fever and great prostration. As the crisis occurred in this case within seven hours after admission to the hospital it was impossible to say whether or not the medication had had any share in the result. He had given carbonate of creosote in very large doses to small children with bronchopneumonia, and had never observed the depressing effect on the heart which creosote itself possesses.

Dr. Smith, in closing the discussion, said that he had gone over the history of pneumonia for many years, and had not found a single instance in which any one in discussing this disease had adverted to the double circulation in the lung, and yet it seemed to him the most important of all the facts connected with

this subject. As this circulation was unique, it did not seem possible to reason from similar disease processes in other parts of the body. It was true that pneumococcus inflammations were present in other parts of the body, but these disease processes did not have anything in their clinical course analogous to pneumonia. Pneumonia was pneumonia because it was in the lung, and the peculiar structure of the lung was absolutely necessary for the existence of pneumonia. The tremendous extent of the process was also worthy of note. Did any one think that with an inflammatory mass in the liver of the size of a consolidation in the lung recovery would take place? Obviously not. When gangrene of the lung occurred it was because a nutrient twig had been involved. It should be remembered that the blood coming to the lung brought with it a variable amount of sodium bicarbonate. The carbonic dioxide of this combination was destined to be thrown out, but in a solid form. Nature had provided for the production of a peculiar acid, made just where it was wanted. This substance was pneumic acid, which formed with the sodium a pneumate of sodium, setting free the carbon dioxide. In pneumonia the production of pneumic acid went on, as could be easily demonstrated. Now, if there were any one thing which the pneumococcus could not tolerate, it was an acid, and in this fact was to be found one of the causes of the crisis. If pneumonia was a simple inflammation, how could the phenomena of the crisis be explained?

**Rupture of Aneurism into Pericardium.**—Dr. L. Faugères Bishop exhibited a fresh pathological specimen showing the rupture of a small aneurism into the pericardium.

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Proceedings of the Twenty-Seventh Annual Meeting, Held at Minneapolis, Minnesota, October 31, and November 1, 2, and 3, 1899.*

*Third Day — Thursday, November 2d — Morning Session.*

(*Concluded.*)

A resolution was offered and adopted, that steps be taken to secure advanced teaching and the giving of diplomas in hygiene, and that recognition of such diplomas be made by sanitary authorities.

Another resolution was adopted, recommending to all governments to set apart such portions of their forests as may be practicable for national parks.

The association established a section to be known as the bacteriological and chemical section of the American Public Health Association. This section is to meet on the day preceding the meeting of the general association.

**Vaccination.**—Dr. William Bailey, of Louisville, narrated in an interesting and instructive manner some points pertaining to the history of vaccination.

Dr. W. C. Woodward, of Washington, D. C., spoke of the accidents of vaccination, some of which arose from impure virus, lack of aseptic precautions, etc.

In the discussion, Dr. E. Licéaga said that revaccination was really unnecessary in Mexico, while in Europe it was imperative because animal virus was used. In Mexico humanized virus was used. His remarks were based on two hundred thousand vaccinations in the republic of Mexico.

Dr. Cabana, of Massachusetts, referred to an epidemic of smallpox which occurred in Montreal in 1885, in which there were ten thousand cases. He thought sterilized virus from the animal was preferable to the humanized virus. He referred to syphilis and other diseases being transmitted by using humanized virus.

Dr. Wright, of Minneapolis, related his experience during six years' residence on the western coast of the Mediterranean Sea. Humanized virus was used there in vaccinating, and he knew of no case of syphilis or any other disease being communicated from one person to another by this method of vaccination.

Dr. Samuel Abbott referred to the rarity of cowpox, and believed that infection in most instances was transmitted by individuals rather than by cows. Very little was known about the remote origin of the infectious diseases.

Dr. William H. Welch, of Baltimore, referred to the septic infections that occurred at the time of or following vaccination.

Dr. Peter H. Bryce, of Toronto, asked in regard to hypodermic injections of vaccinia, to which Dr. W. C. Woodward replied that Dr. Kinyoun had tried it in numerous cases with satisfactory results.

Dr. Charles V. Chapin called attention to a report of the New York board of health for 1896, in which reference was made to experiments with the subcutaneous inoculation of vaccinia, saying it was not so reliable as inoculation by scarification.

Dr. Samuel H. Durgin reported a case in which subcutaneous injection of vaccinia was resorted to, the constitutional disturbance being the same as that observed by the usual method of vaccination. This case was observed some twenty or more years ago.

Dr. Frederick Montizambert, of Ottawa, Can., favored bovine instead of humanized virus, principally for the reason that if syphilis or any other disease should follow vaccination by humanized virus, the anti-vaccinationists would have an argument for the condemnation of vaccination generally.

Dr. Charles F. Roberts, of New York City, also spoke in favor of bovine virus for vaccinating purposes.

Dr. Benjamin Lee narrated an instance in which several members of one family were infected with syphilis by impure virus, the vaccination having been performed in this case by a drummer, not a doctor.

Dr. James F. Kennedy, of Des Moines, Iowa, said the president of the anti-vaccination league lived in his State, and it was claimed by the anti-vaccinationists that not only syphilis but tuberculosis was transmitted by bovine inoculation; but he did not think so.

Dr. Louis Laberge, of Montreal, said that with humanized lymph, if proper aseptic precautions were observed, there was practically no danger of transmitting disease.

Dr. Liston H. Montgomery, of Chicago, asked in regard to tetanus following vaccination, and if pathogenic germs were found in the discharges.

Dr. Cabana reported two cases of tetanus following vaccination.

Dr. Woodward reported another case.

Dr. H. M. Bracken said that physicians should take cognizance of the length of time following infection. In two cases of tetanus which he had observed the disease developed on an average of three weeks after vaccination. These persons were very dirty, and he believed the vaccination had nothing to do with the development of that disease.

**The Official Definition of Diphtheria.**—Dr. H. W. Hill, of Boston, read this paper. He said that the first factor in the production of the disease was the patient, and the second, the bacillus of diphtheria. The disease of diphtheria was existent only when the active diphtheria bacillus, producing recognizable lesions, was present. The presence of diphtheria bacilli without the production by them of recognizable lesions did not constitute this disease; nevertheless such pa-

tients might be a source of possible infection to others. The necessity of isolating persons suffering from the disease, in order to prevent its spread, had long been recognized. In order to place the matter on a definite basis it was suggested that this definition be recognized by so wording all regulations relating to the supervision of diphtheria that, in so far as might be advisable for the protection of the public health, the demonstration of the presence of the diphtheria bacillus should be sufficient to empower health authorities to proceed with measures directed to prevent its dissemination. He suggested that such phrases occurring in regulations as "persons suffering from diphtheria," or "cases reported as diphtheria," should be modified to read "persons suffering from diphtheria or infected with diphtheria bacilli," and "cases reported as diphtheria or as infected with diphtheria bacilli." It seemed to him that a simple change of wording would give the necessary power to health authorities, while absolving them from any charge of wrenching terms to suit misunderstood conditions, such as were sometimes, although unjustly, brought forward.

**State Cancer Laboratory.**—Dr. A. Walter Suiter, of Herkimer, N. Y., offered the following resolution, which was adopted:

*Whereas*, The State of New York has taken a decisive step in advance by the grant of an annual appropriation for the establishment and maintenance of a laboratory with all modern appliances for the persistent prosecution of studies in the etiology of cancer; and whereas results have already been obtained which lead to the hope that the discovery of the etiological factor in the production of this much-dreaded disease may be attained; therefore, be it

*Resolved*, That the association approve of similar efforts to that end, that State and national patronage in special and general scientific research may be universally established.

**A National Home for Lepers.**—Dr. H. M. Bracken, of Minneapolis, presented the report of the committee on a national home for lepers in the United States. He stated that inasmuch as the Congress of the United States had passed a law for the appointment of a commission of medical officers of the Marine-Hospital service to investigate the origin and prevalence of leprosy in the United States, and to report upon what legislation was necessary for the prevention of the spread of the disease, he would recommend that the committee of the association be continued to report at the next meeting. He stated that the Ramsey County Medical Society and the Minnesota Academy of Medicine had already taken action urging upon the United States government the necessity of establishing homes or colonies where lepers could be segregated, thus protecting the general public and at the same time furnishing these sufferers with a comfortable home and suitable medical care.

**Definition of an Epidemic.**—Dr. U. O. B. Wingate, of Milwaukee, Wis., presented the report of the committee to define what constitutes an epidemic, and the following definition was recommended to the association for adoption: "An epidemic is an outbreak of a communicable disease or infectious disease, affecting a dozen or more individuals in quick succession before the recovery of the first case, whether arising from a single focus or from several foci in the neighborhood." This definition was not satisfactory to the association, and the matter was therefore referred to another committee to be appointed for the ensuing year.

---

*Fourth Day—Friday, November 3d—Morning Session.*

**The Treatment of Garbage and Excreta in Military Camps.**—Dr. Benjamin Lee, of Philadelphia, presented this paper. He spoke of flies as factors in the causation of disease. He also referred to the portable furnaces which were now being used by the United States government at Havana for the destruction of garbage, with gratifying results. Two additional papers were presented on waste disposal and its advances.

**Diphtheria Antitoxin.**—Dr. C. H. Jones, health commissioner of Baltimore, related his experience in the treatment of diphtheria with antitoxin and formaldehyde, which showed a great decrease in mortality by the use of these agents. He said that the health department of that city had not lost a case of diphtheria which was treated with antitoxin within the first two days of the disease.

**Report of the Committee on Demography and Statistics in their Sanitary Relations.**—Dr. C. L. Wilbur, of Lansing, Mich., read this report. He stated that with the completion of the work relative to the nomenclature of causes of death, a larger part of the time of the association should be devoted to other subjects of vital statistics, which had been neglected to some extent in recent meetings. Technical papers, dealing with the best methods of collection, tabulation, and presentation of vital statistics, should be presented, but papers of a different class, relating to the employment of vital statistics in practical sanitary administration, should also receive consideration. Some systematic effort should be made to extend the number of registration States, and to insure that all States and cities adopting methods of registration should comply with certain necessary standards of efficiency, which it might well be the province of the authorities connected with the association to formulate for convenient reference. Lastly, no efforts should be spared to raise the general standards of vital statistics and to increase their value in the public mind as an absolutely essential part of modern sanitary science, and the basis of public health work. Vital statistics should be systematically taught in our medical schools, with special reference to their practical use by health officers and students of the prevalence of disease. The practical study of mortality statistics was a necessary part of the work of the medical officer of health, and its reputation and character should not be diminished by withdrawing it in any case from medical direction.

**Officers Elected.**—The following officers were elected for the ensuing year: *President*, Dr. Peter H. Bryce, of Toronto, Ont.; *First Vice-President*, Dr. H. M. Bracken, of Minneapolis, Minn.; *Second Vice-President*, Dr. Juan Brena, of Zacatecas, Mexico; *Secretary*, Dr. Charles O. Probst, of Columbus, Ohio; *Treasurer*, Dr. Henry D. Holton, of Brattleboro, Vt.

Indianapolis, Ind., was selected as the place for holding the next meeting.

---

**Vaccination with Six Punctures.**—An innovation in the operation of vaccination for smallpox has been practised in Bengal during the past year. The six-puncture system has been introduced, and the decrease in the number vaccinated is perhaps explained by this change. It is thought that the plague scare has contributed to the decrease, but it is much more likely that the extra two points have been objected to. In some places it is said that they were looked upon as in some way connected with plague inoculation. In Calcutta alone the decrease was 12,704 in the number of operations. It is difficult to see on what reasonable grounds these changes were introduced, as it has been conclusively shown that four points, when followed by an average success in "takings," afford a very high degree of protection. The multiplication of points is much more likely to bring the operation into discredit.—*Lancet.*

## Surgical Suggestions.

**Secondary Hemorrhage.** — We may enumerate the causes of secondary hemorrhage as follows: (1) Septic infection or sloughing of the artery, due to infection of the wound, of the ligature, or of the blood clot; (2) yielding of an arterial cicatrix; (3) division of the inner coats of an artery, weakening its walls; (4) advanced disease of the arterial walls; (5) cachexia, hæmophilia, chronic renal disease, diabetes; (6) plethora; (7) increased force of the ventricular contractions; (8) punctured wound or incomplete division of an artery; (9) proximity to the ligature of a large branch; (10) special thinness of the outer coat of an artery; (11) wound of a branch arising just below a ligature in continuity; (12) faulty ligature.—A. Pearce Gould, in Treves' "System of Surgery," vol. i., p. 544.

**Treatment of Injured Arteries.**—The important points to be specially borne in mind in the treatment of injured arteries are: (1) To secure the total occlusion of every wounded artery; no attempt must be made to obtain healing of the wound in the vessel without obliteration of its lumen. (2) When nature has closed the end of a divided artery, the surgeon should not interfere with it.—A. Pearce Gould.

**Vaginal Hysterectomy** with the ovaries left *in situ* is followed by much less nervous and physical disturbance than when the ovaries are removed and the uterus is left, or than when they are all removed at the same time.—J. T. Johnson.

**Leucoplasia Buccalis.**—Leucoplasia developed in old syphilitics should be considered, as tabes and general paralysis of a specific origin, a parasyphilitic affection. In this condition, specific treatment should not be employed, for it is not only useless but harmful and dangerous. The only treatment capable of avoiding epitheliomatous degeneration, which so frequently occurs, is early surgical intervention.—Legrand.

**To Remove Silver Stains.**—(1) The cloth is immersed for five minutes in a solution of twenty-five parts of sodium chloride and ten parts of corrosive sublimate in two litres of water, and is then rinsed with pure water. (2) A twenty-per-cent. solution of ammonium chloride in water is prepared and enough tincture of iodine added to color it yellowish-brown. The fabric is immersed in this for five minutes, the liquid diluted with water, and there are then added a few crystals either of sodium sulphite or hyposulphite, or a little ammonia. If after thorough contact the stains are still visible, the treatment must be repeated. (3) The stains are moistened with javelle water, and the cloth is washed after five minutes with water containing 0.5 per cent. of hydrochloric acid.—Credé.

**Thiersch's Grafting in Varicose Ulceration of the Leg.**—In order to insure success in cases of chronic ulceration of the legs it is absolutely necessary—(1) previously to bring the ulcer into an aseptic condition; (2) to remove the edge of the ulcer before applying the grafts; (3) to treat varicose veins or other causes of the ulceration; (4) to insist upon the patient resting the leg for a considerable period afterward until the adhesion of the grafts has become firm.—J. E. Platt.

**Pelvic Operations.**—The first question which naturally presents itself is this: Is there any difference between operations upon the pelvic organs of women and operations in general? If you examine the statistics you will be at once struck with the number of patients operated upon for pelvic disease, who show insanity, neurasthenia, and other nervous troubles following operations and probably resulting from them. Some writers have come to the conclusion that these operations are peculiarly liable to be followed by such phenomena; but if you come to analyze the cases more closely you will find that these operations are performed upon persons whose general health is greatly impaired.—Moyer.

We make a mistake as gynæcologists, perhaps, in sometimes promising too much as the result of local treatment of pelvic disease. We certainly need to give due heed to the claims of the patient's general health, treating not the pelvis alone, but the woman as a whole.—Montgomery.

**Strangulated Hernia.**—Surround the tumor with vaseline, elevate the pelvis, flex the thighs, and pour ether upon the constricted neck. Depletion of tissue, shrinkage, relaxation, render reduction possible.—*Med. Rev.*, September 30th.

**A Glycerin Soap** for clinical purposes, which does not chap the hands:

℞ Green soap,
Glycerin. . . . . p.æq.
Mix well.

**Surgical Hints.**—In the class of fractures in which there is detachment of processes and apophyses, we very often fail to get crepitus, as in transverse fractures of the patella, fractures of the olecranon and coronoid processes of the ulna, and of the coracoid and acromion processes of the scapula.

The severity of the symptoms of intestinal obstruction usually bears a relation to the suddenness of the attack. The more sudden it is, the worse for the patient, and the greater the need of immediate interference.

A truss for inguinal hernia is of no value unless the pad lies over the internal ring in a permanent position, notwithstanding the changes in posture of the body, and unless the pressure is just enough to hold the hernia, and no more or less.

In all intraperitoneal operations the rule is to move the bowels early, but if there is shock with a fast and irregular pulse and nervous disturbance, morphine is indicated at first, just enough to quiet the nervous system. After this has been accomplished the bowels may safely be moved.

It is a mistake to think that cancer of the uterus is always painful. If a suspicious growth is seen, the question of pain should not influence the diagnosis. Any flow of blood after the menopause demands immediate careful investigation, but cancer of the cervix has been observed in quite young women.

When you succeed in passing a catheter into the bladder in cases of considerable retention, do not empty it entirely or too suddenly, as it may give rise to hemorrhage, which is sometimes very profuse, or to severe cystitis, or even to urinary suppression and death. It is well to partially plug the lumen of the catheter so as to allow the urine only to dribble out.

If a child complains of pain anywhere about the lower extremities, or limps in the slightest degree, examine the hip-joints as a matter of routine. In that way many unsuspected cases will be early revealed.

In an inflamed cervix uteri the tenaculum holds quite firmly; in carcinomatous ulceration it tears out readily, with much bleeding; and in cystic degeneration, while it usually tears out readily, it lets out thin mucus with or without blood.

In old people quite a considerable degree of cystitis may exist without giving rise to symptoms. The microscopical examination is in such cases quite indispensable.—*International Journal of Surgery*, May.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE WAR—CONSULTING SURGEON TO THE R. A. M. C. SIR W. MACCORMAC—THE INFECTIVITY OF CANCER—"SLEEPING-SICKNESS" OF THE CONGO—THE ARCHBISHOP TO STUDENTS—SCHOOL ENTRIES—THE MUZZLING ORDER—GUILD OF ST. LUKE.

LONDON, October 27, 1899

"BELLUM, horridum bellum"—all our talk is of the war. Doctors are citizens, and their patriotism is as pronounced as that of any class. In the excitement of the South African struggle the arrival of a case of plague at Plymouth attracted very little attention on the part of the public. Of course such an event was anticipated by the profession, and the sanitary authorities were prepared. There is, however, a point of interest in this case—the period of incubation. The crew were in good health on leaving Bombay, and sixteen days elapsed before the man complained of illness. Did he take it in the Mediterranean, or where?

As to the war it was announced in the House of Commons on Tuesday that Sir William MacCormac will shortly proceed to South Africa in the capacity of consulting surgeon to the Royal Army Medical Corps, and that he will be accompanied by two other civil surgeons. It is stated that the idea of employing civil surgeons to co-operate with the military medical officers proceeds from the army medical department, and that Sir William's name was mentioned as one who would be specially suitable. On hearing this he at once placed his services at the disposal of the War Office. It is not a new thing for civil surgeons to help in time of war, as they did so in the Franco-German and Russo-Turkish campaigns. With us, however, it is a new departure, though it may be a natural sequel to the home defence mobilization scheme under which civil surgeons are attached to base hospitals. If the plan is good no better man could have been selected than the esteemed president of the College of Surgeons. Sir William has experience of war. He was surgeon to the Anglo-American ambulance in the Franco-German conflict, and he rendered invaluable aid in the Servian war of 1876. He is a *persona grata* with his brethren, both civil and military. His health was some time ago giving his friends uneasiness. We all hope the South African climate may do him good.

On Monday the Medical Society had under discussion a paper by Dr. J. W. Washbourn and Mr. Bellingham Smith on "The Infectivity of Malignant Growths." The conclusions at which these authors had arrived were that such growths are local in origin but possess the power of infecting adjacent and distant parts of the same individual; that inoculation may take place from one part to another of the same individual, apart from transmission by the natural channels; that there is evidence that one person may be infected from another; that there is also experimental evidence that growth may be transferred by inoculation from one animal to another of the same species. So far a considerable number would probably agree who might hesitate to accept the further conclusions, which were to this effect: that bodies resembling micro-organisms are found in malignant growths and have been regarded as belonging to the protozoa or the blastomycetes; that a new growth with the structure and behavior of carcinoma has followed in at least two instances inoculation with a form of blastomycetes, and that these experiments are highly suggestive that the bodies found in cancer may be the cause of the disease, though evidence is wanting that the two are directly associated.

Dr. MacFadyan pointed out how necessary it is to distinguish between epithelial and connective-tissue growths. He suggested that some growths described as sarcomatous might rather be the result of reaction of the tissues to living irritants. The structure of sarcomata and many bacterial growths could not be called dissimilar, and actinomycotic tumors used to be described as sarcomata. As to transplantation, were there any examples occurring with lesions known to be parasitic?

The "sleeping-sickness" prevalent on the Congo, and which seems to be rather on the increase, has been the subject of some investigation here. You may remember that two Congo boys who were brought to this country died of this curious complaint. Dr. Mott, pathologist of the London County Council, investigated the state of the nervous system in these cases, and brought his results before the Pathological Society, illustrating his statements by lantern slides and microscopic specimens. He examined the brain, spinal cord, pituitary body, and spinal ganglia. He found signs of a leptomeningitis and encephalomyelitis in both cases, extending throughout the central nervous system, but especially in the medulla and base of the brain. Dr. Mott thought the symptoms of the disease could be best accounted for by supposing that the activity of the neurons as a whole was affected by some toxic product in the blood or in the cerebrospinal fluid, and that this product occasioned great proliferation of mononuclear leucocytes beneath the pia and in the perivascular lymphatics. The liver, spleen, kidneys, lungs, lymphatic glands, and duodenum were also examined, all except the last two giving negative results. The glands were enlarged, owing to the increase of leucocytes; the duodenum showed a large number of lymphocytes and proliferation in the lymphoid nodules. The facts were of interest in contrasting the disease with general paralysis, which many consider to be a primary meningo-encephalitis; although the appearances of inflammation were equally intense and more widespread than in any case of general paralysis which Dr. Mott had seen, yet the cellular changes were slighter—an argument in favor of the view that progressive paralysis of the insane was a primary disease of the neuron with secondary inflammatory changes.

On Wednesday the archbishop of Canterbury presented the prizes at St. George's Hospital, and addressed the students in his homely, earnest way. He told them he did not feel quite certain that in every case the doctor did just right; but he was quite certain that, taken as a whole, the blessings which medical science had conferred on humanity took rank with the very highest benefits that could be bestowed on man. By using his brains as he ought, a man not only gained knowledge but the power of using his knowledge, a power they might acquire by keeping an open mind when in practice. A doctor who fancied he knew all that could be taught was really going back, for science was always going forward. Further, he was losing ground within himself, for he was failing in the keen perception which he once had.

Hull is still suffering from smallpox. Some forty cases have been admitted to the hospital during the week. More than three hundred cases have occurred in the town during the epidemic—about six months.

The entries at the medical schools seem rather under the average. The teachers are somewhat disappointed, but men in practice see no cause for regret. There is no fear of any lack of help for the public from the overcrowded profession.

The order for muzzling dogs in London is revoked, as from to-day. There is no doubt this order has

been effectual against hydrophobia, and the ministry deserve thanks for maintaining it in spite of the outcry of selfish owners of dogs. It will be necessary to keep up the rule as to imported dogs, or we may soon have rabies brought into the country again.

The Guild of St. Luke has paraded itself once more in the glory of clothes, and the Bishop of Stepney preached on the occasion to the assembled doctors. He told them there is a science of theology as well as of medicine.

## FAITH CURE AND THE LAW.

To the Editor of the Medical Record

Sir: Your correspondent, Dr. N. C. Steele, in the Medical Record of October 7 1899, makes a plea for liberty of action on the part of mankind in the selection of the person who shall treat him in sickness. The doctor shows a very liberal spirit, and his plea seems to be founded upon justice, but there is just one element in the problem that he fails to mention. No law can compel a man to employ any particular kind of medical attendant in sickness; no law can prohibit his employment of any particular kind. But what the law can do is to compel all persons who undertake to heal the sick to acquire a certain amount of knowledge of the human body, its structure, its functions, the diseases to which it is subject, their causes and natural history, and the conditions which imperil life. Persons who have complied with this requirement of the law are then at liberty to practise "Christian science," "faith cure," "regular" medicine, "homœopathy," "eclecticism," "voudooism," "charms," "osteopathy," or any other old thing, and Dr. Steele or any other citizen would be at full liberty to elect the method that suited his fancy. The law does not undertake to bar the citizen from making a perfectly free choice of the method of treatment and the person who shall administer it, providing always that the person who so professes to treat the sick has complied with certain reasonable requirements.

That all who assume the responsibility of treating the sick, and make certain professions of skill in so doing, shall comply with the standard of requirements, organized society has a right to demand. If it demands it of one, it must demand it of all. There cannot be one standard for "drug-healers" and another for "faith-healers." Organized society cannot accept the alluring fiction that there is no such thing as disease. We know that it is not true. To assume that it is true, or to permit a certain fanatical sect to act upon such erroneous belief, is to share in the responsibility for the neglect of certain well-known prophylactic measures, which neglect would endanger the lives of many in a community. The life of no individual belongs to himself exclusively. Organized society, the community, has an interest in the life of each individual of the community. If this were not so, there would be no public hospitals for the free cure of the sick who are unable to care for themselves. The founding of such hospitals is not a philanthropic enterprise; it is an expression of the selfish and common interest which the race has in the propagation of the race, in the conserving of the sum total of human life, that none shall unnecessarily go to waste.

Laws to regulate the practice of medicine (the healing of the sick) are of like character. They are not for the purpose of limiting one's choice. They are for the purpose of safeguarding one against imposition. In society's effort to protect itself, certain regulations (called laws) have been adopted which demand that those who profess to be competent to become arbiters of health and life shall possess a certain standard of qualification. Society has determined what that standard shall be. It is no hardship to demand that all shall come up to it. But that is as far as organized society goes, because that is as far as accepted doctrines permit it to go. Beyond that, all is free. Dr. Steele is free to make what choice he will; those who practise the healing art are free to practise what they will. There is no restraint upon any one.

Charles Gatchell, M.D.

162 Thirtieth Street, Chicago.

## LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

DECREASE IN THE BIRTH RATE—HOSPITAL SYSTEM—RARITY OF CERTAIN DISEASES—THE "GEORGIA MAGNET" ON HER TRAVELS.

Auckland, September 28. 1899

The decrease in the birth rate of the Australasian colonies, and especially of New Zealand, which is the lowest of all, is beginning to excite a good deal of attention. In a former letter I touched on this question. Since I wrote, another official year-book has been issued (for 1898), and by this it appears that the birth rate is still diminishing, and touched 25.74 per thousand of population. In 1880 it was 40.78. It was thought that as there was a temporary increase in the marriage rate in 1897, there would have been at least a corresponding increase in the birth rate. But the fact is that the young women will not have more than two children at the outside, if they can help it, and some of them will not have more than one. And they take every possible means to prevent conception, and if that does occur then they either produce abortion or get some one else to do it for them. A few weeks ago I was consulted by a young unmarried woman, aged twenty years, who calmly explained to me how she had used a speculum, and introduced a silver catheter into the uterus herself twice. The first time she passed it in two inches, and the second time two and a half inches. This virtuous young female is now married, and operated on herself to prevent the unpleasantness of having a child too soon after marriage.

It would be interesting to us here to know the birth rate of the different American States, if such statistics are published in any accessible form. Owing to the enormous use of preventives, the proportion of illegitimate births is slightly diminishing.

As our hospital system differs very greatly from that of the mother country, it may interest some of your readers to know how we manage. The hospitals for the insane are entirely maintained by the colonial government, with the exception of one very small private asylum for paying patients only. The medical superintendents and all the other officials are therefore government servants. The asylums are all overcrowded, but a vote has been taken this year to remedy this. Nobody except the officials knows much about the asylums, but it is believed that they are fairly well conducted. An inquest is held, by law, on every death in an asylum or jail.

The general hospitals are of two kinds. Those in the mining districts are supported in part by the voluntary contributions of the miners and residents in the district, whose subscriptions are subsidized by a government grant of twenty-five shillings for every twenty shillings subscribed. They are all small hospitals, and are managed by boards chosen by the subscribers. The subscribers have a right to admission in case of illness or accident; other patients are expected to pay, if able to do so. Any deficiency in the funds is made good by a contribution of the Charitable Aid boards, obtained from rates.

The larger hospitals are all maintained out of the

public funds, either by grants from the central government, or by the funds derived from rates of the Charitable Aid boards, who by law can strike a rate for the hospitals. Some of the patients pay four or five dollars a week toward the cost of their maintenance and medical attendance. This can be recovered by a summons if the patient is able to pay and neglects or refuses to do so. A weak point in the system is that though the general government in all cases contributes more than half the cash, it has no official representatives on the boards.

The medical staff, nurses, servants, and other officials are all elected by the board, and may be dismissed by them. The appointments are mostly annual, though in some cases the honorary visiting staff is appointed for three years. The staff of the larger hospitals, which contain from one hundred to one hundred and fifty beds, consists of one or more paid residents, and several honorary physicians and surgeons, together with an ophthalmic surgeon, one for female diseases, and sometimes other specialists. One of the hospitals, Dunedin, has a small medical school attached, and manufactures a few practitioners. They are not held of much account unless they go to Europe to complete their education.

The fact is, that a man who studies medicine only in this colony cannot get a practical knowledge of disease. We have not a sufficient number of cases, and of some diseases, common enough in the old country, we have so few examples that a man may pass years without seeing a case. Take hysteria, for instance; a regular fit of hysterics is quite a rarity here. In twenty-six years' practice I have been called to only two cases, while in a London hospital I never passed a day without seeing two or three. Bright's disease again is very much rarer here than in England, and so are all tuberculous diseases. The fact is, that the population generally is sober and well-fed, and the houses are not, even in the largest towns, built very close together, so that we do not produce the diseases arising from the intemperance, the foul air, and the starvation of the large European cities.

The great defect in our hospital system is the mode of appointing the honorary visiting staff. They are all what we call in England general practitioners; that is, they attend midwifery cases, and take every kind of disease, medical or surgical, indiscriminately. They are called physicians and surgeons, but there is no such person as a pure physician or surgeon in the colony. The towns are too small; our largest city with its suburbs contains only about fifty thousand inhabitants. The staff being appointed by a local board, no question of professional skill or even competence is ever entertained for a moment; private interest is everything.

The hospitals in the larger towns are well fitted out with instruments and operating-rooms for aseptic surgery. There is a perfect mania for operating, and every woman who suffers from leucorrhœa, if she gets into some surgeon's hands, will be curetted, and an Alexander done at least, if she does not have the whole genital apparatus extirpated. It surprises me that no one (as far as I know) curettes the vagina for chronic vaginitis. "Why not?" as the March hare said. If you scrape away the mucous membrane of the uterus for chronic endometritis, why not scrape away that of the vagina for chronic vaginitis, and that of the rectum for chronic dysentery? This suggestion is copyrighted.

We have had a visit from a fair countrywoman of yours, Miss Alice May Abbot—the Georgia Magnet. Her performances have "time and again" been noticed in your paper, her manager writes to me, so that I need not refer to them particularly. She succeeded in hypnotizing a lot of gushing men, old, young, and middle-aged, and convincing them that they could not lift her from the floor with their arms extended at full length, and her pretty fingers tickling their necks inside their collars. She so thoroughly hypnotized one of our *confrères* that, after the performance was over, when he took her temperature he announced it as 93.5° F., whereupon I uttered a groan of incredulity. The audience of course saw nothing in it. We certainly are a soft lot in New Zealand.

The annual meeting of the Australasian Medical Association has just commenced in Brisbane. This is a branch from the British Medical Association.

## LETTER FROM THE FALKLAND ISLANDS.

(From our Special Correspondent.)

STATISTICS — CLIMATE — PREVAILING DISEASES — SURGERY — PEAT WATER AS A PRESERVATIVE.

STANLEY, FALKLAND ISLANDS, September 14, 1899

THE population of the Falkland Islands is approximately about 2,000. In 1898 the births were 64, percentage 3.6; deaths 27, percentage 1.56. The cause of the latter being high was a sad boating accident whereby ten lives were lost. As a matter of fact death by drowning is unfortunately too frequent, owing to the stormy nature of the climate and the extreme coldness of the water when a boat is capsized, which appears to paralyze every effort of the swimmer. The season when sickness is rife is the early spring. This is owing largely to the saturated condition of the peat bogs and the impossibility of the water freeing itself until hydraulic pressure takes place in the form of a peat slip; and the advent of spring, when the strong westerly winds produce evaporation—hence summer and the major portion of the winter are healthy. The months when influenza is prevalent are July and August. The meteorological conditions of the seasons have much to do with sickness. In cold, damp weather influenza takes root, also rheumatism, which has always been unfortunately too frequent.

The drainage of the settlement is most defective, there being no intercepting drains to catch the storm or surface water from the hills which surround the settlement on the south side; the ordinary main drains and those leading from private dwellings leave much to be desired. Notwithstanding this drawback the health of the settlement is excellent, which speaks well for the health-giving qualities peculiar to these islands. There is a total immunity from all tropical and malarial diseases, nor can they at any time be imported as the thermometer ranges from 30° to 50° F. in winter, and from 40° to 65° F. in summer; but the latter is of very short duration, as it is not uncommon after a morning at the above temperature for the thermometer to fall to 38° F. in the afternoon.

Scrofula is common but not indigenous; this climate is antagonistic to tubercle, in consequence of the entire absence of want or destitution of any kind, the abundance of highly nitrogenized food in conjunction with the concentrated form of oxygen. Ozone is the prophylactic. Syphilis is occasionally met with either in the secondary or tertiary form, rarely in the primary, as the social evil is almost unknown. Cancer, whether as fungus hæmatodes, melanosis, or scirrhus, is rare. I have had six cases of the latter and one of fungus hæmatodes during my residence here. Diseases of the nerves are also rare. In children chorea is occasionally seen, but only three cases of meningitis to my knowledge have occurred. Diseases of the respiratory organs, such as bronchitis, pneumonia, and asthma, are infrequent—the former as a sequela of influenza, or neglected cold.

Surgical injuries are very common, owing to accidents on board ship, or falls from horseback. They consist of fractures of the femur, tibia, or Pott's fracture of the fibulæ, fractures of the arm, forearm, Colles' fracture of the wrist, clavicle, inferior maxilla, base of skull. I have alone and unaided performed several capital operations, *i.e.*, right shoulder-joint, forearm, leg below tubercle of tibia and lower third, also Chopart's and Syme's on the foot, hand, and phalanges.

I mention these cases specially to show the aseptic nature of the climate, as every operation performed was an unqualified success. The bacilli are chilled by the cold reception in these islands on the fringe of the Antarctic.

I may mention in closing that I knew the late Admiral Spotts and dined with him and Captain Weaver on board the United States flag-ship *Brooklyn*, the evening previous to his very sudden death. I went on board when his death was announced the following morning, and, in conjunction with the doctors on board, viewed the body. He had a very large and representative funeral. Again it became my duty as president of the board of health to give permission and assist at the exhumation of the body in the early part of this year, when the United States cruiser *Badger* arrived here. The body was in a perfect state of preservation, no change whatever even in the features—in a word, little different from when I saw him alive seventeen years previous. This was owing to the preservative effects of the peat water, which had burst the coffin and saturated the body.

## THE TECHNIQUE OF BASSINI'S OPERATION.

To the Editor of the Medical Record.

Sir: I wish to offer my congratulations to Dr. Andrews, of Chicago, whose article upon Bassini's present technique appears in your issue of October 28th. In beautifully clear and explicit language he has detailed many little points of interest to the surgeon; and it is only by just such study of minute technique that advances are made.

Let us hope that in a later paper he will describe Bassini's method with femoral hernia. If he does this, perhaps he will also give the exact composition of the lime-and-starch mixture used for fixation bandaging; also the antiseptic solution out of which the operator takes the glycerin-boiled silk for use.[1]

This matter of the suture material is one that is by no means settled. Several surgeons now can claim a distinctly better proportion of permanent cures to relapses than twenty to one—the percentage, or "less than five per cent.," claimed for Bassini; and it may well be that his use of silk is to some extent responsible for this.

Schimmelbusch, von Bergmann's famous assistant, in his work "The Aseptic Treatment of Wounds," affirms that silk, absolutely sterile, placed by sterile means within sterile wounds, occasionally, if rarely, "after a long period of time" produces pus. This shows that it then acts as a foreign body of an irritant nature, and the phagocytes are sent in myriads to try to devour it. They fail. Pus is the result; and it is none the less objectionable because devoid of microbes. This may happen only after months or perhaps years. It of course seldom occurs; but it may account for one or two per cent. of relapses. Schimmelbusch says of such silk: "It simply remains a foreign body in the tissues, of which the organism endeavors to free itself as soon as a favorable opportunity presents."

What is true of silk in this regard is also true of "silkworm gut" (which is simply the *un*spun fluid of the silkworm, which if spun would have been silk). Dr. Edebohls has very frankly and honestly come forward to withdraw his former commendation of buried silkworm-gut sutures—and for this same reason, based upon his longer experience with them.

Here in New York most of the surgeons have quite discarded non-absorbable materials for buried sutures and for ligatures. I think that most of us use, for the deepest two rows of Bassini's technique, chromicized large catgut. This remains many weeks unabsorbed, but finally disappears. Dr. Weir's experiments would seem to show that well-chromicized catgut lasts at least as long as kangaroo tendon. If this is so, no reason of importance remains for continuing to employ the latter, which is so much more expensive. It is nevertheless far preferable to silk, since the latter is rarely absorbed.

The idea that the largest sizes of catgut cannot be sterilized is of course erroneous. Boiling in absolute alcohol, under pressure, as Fowler first advised, will do it. As to even ordinary, *non*-chromicized catgut, "the fear that it may [in a wound] be too rapidly absorbed, as has occasionally been expressed, is not well founded; it persists much longer often than is desired" (Schimmelbusch).

Bassini's use of silk sutures for the skin, to be cut and drawn out on the eighth day when the dressings are changed, would seem indefensible. Quite fine, aseptic catgut, which would be absorbed by that time, would save the patient needless pain in this regard.

Perhaps the commonest cause of a relapse, next to infection, when a comparative beginner is at work, is neglect to free sufficiently, upon both superficial and deep surfaces, the conjoined muscles from the tissues nearest them—and dependence upon the deepest row of sutures to keep these muscles dragged down to Poupart's ligament. In surgery, as in matrimony, unwilling union is pretty certain to be followed in time by a divorce. By the handle of the scalpel the conjoined muscles should be completely freed, for inches if need be, until they will lie, quite without effort, in contact with the ligament. Doubtless Bassini avoids the mistake indicated; but it was hardly emphasized in the article under discussion.

I have his original article upon his method of radical cure, and faithfully followed his description in writing up hernia for Wood's "Handbook," in which I also detailed some twenty other methods; but, if I remember correctly, the point made by Dr. Andrews at this time is new—namely, that Bassini by his first row of stitches now "inverts the upper or muscular segment like a Lembert suture," producing "an overlapping or imbrication here, giving broad surfaces of union." It is also certainly well worth a thought.

Numerous other questions of technique, especially as to the treatment of the sac and placing of the cord, will occur to every one, but cannot properly be studied within the limits of a letter. I can only allude in conclusion to the interesting description of the huge ward of the Spedale Civile, capable of holding twice ninety-six beds; for, as Dr. Andrews describes it, only a low screen separated the one group of ninety-six (or with a capacity for that number) from the other; "so that the two rooms were in reality one immense chamber." To this Dr. Andrews "can see no real objections" unless from "difficulties in administra-

[1] In this country sterilizing silk by boiling in glycerin has been commonly discarded in favor of boiling in water, which is certainly as effective. It was Miquel of Paris, who in 1880 suggested the use of glycerin heated to 140° C. Redard among others refers however, to the "intolerable odor of boiling glycerin, as precluding its use."

tion and nursing." To the writer it would seem that there is a different and most serious objection to such an enormous ward, namely, that one suffering patient can by his groans, or by screaming out in a nightmare, spoil the sleep of a great number of others; some of whom may even be placed in jeopardy of their lives, if in a critical state, by a sudden fright or by broken rest. Plainly, the smaller the wards the better for the patients—if the air space is relatively the same in either case.

A very large ward of this kind is to be found in the new United States Naval Hospital in Brooklyn—in most other respects, and particularly in its operating-room and equipment, a credit to the government.

Once more, the expression of my cordial appreciation to Dr. Andrews, with the hope of another article of equal value from his pen.

ROBERT H. M. DAWBARN, M.D.

## THE VAGINAL OPERATION PREFERABLE FOR INTRALIGAMENTOUS CYSTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In to-day's number of the MEDICAL RECORD I find myself credited, during a discussion on "Ovarian Cystoma Complicating Pregnancy," before the Obstetric Section of the Academy, with the statement that it is "a great mistake to operate on an intraligamentous cyst, whether the woman was pregnant or not, provided it did not extend up very high." Of course I expressed no such opinion, and I do not wish to go on record as entertaining so absurd a view. What I did say substantially was, that in my opinion it was a mistake to operate on an intraligamentous cyst from above, that is, by the abdominal route, unless it extended high up into the abdominal cavity, for when such cysts are entirely intrapelvic they can be much more easily and safely evacuated and even enucleated through the vagina, whether during pregnancy or even during labor, if in the way, or in the non-pregnant condition. The omission in the report of the distinction between the abdominal and vaginal operation constitutes the absurdity of the statement, for the correction of which I venture to trespass on your valuable space. I may be permitted to add that, in my experience, the evacuation by free incision of intraligamentous ovarian cysts, with or without enucleation of the sac, is far safer and easier, and vastly less dangerous, while equally curative (gauze drainage and packing), when performed through the vagina, than when carried out by the abdominal route. Only in large intraligamentous cysts, which have become chiefly intra-abdominal, do I think the operation from above advisable. I know of no abdominal operation which is likely to present more technical difficulties, and consequently more risks to the patient, than the enucleation of an intraligamentous ovarian cyst and the stitching of the flaps of the broad ligament to the abdominal wound. It is in these cases that pan-hysterectomy often becomes necessary. These risks can be avoided, to a great extent, by the vaginal method.

When the diagnosis between a small intraligamentous ovarian cyst and an ordinary pelvic ovarian cyst is doubtful, I should prefer opening the abdomen, and, if the cyst proves to be intraligamentous, closing the abdominal incision and operating per vaginam as already described, rather than to proceed to remove the cyst by the abdominal route. This applies with even greater force to an ovarian abscess when it proves to be intraligamentous.

PAUL F. MUNDÉ, M.D.

20 WEST FORTY-FIFTH STREET.

## OPIUM TREATMENT IN APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: On page 683 of the MEDICAL RECORD for November 4, 1899, Dr. Rochester is quoted as saying that "personally he was one of those who believed that acute appendicitis should not be operated on in the acute stage, but should be treated with large doses of morphine, according to the old method of Alonzo Clark." I shall be very glad to treat my acute appendicitis cases in this way, if it is the best way. Every responsible physician and surgeon will be very glad to give up his other methods and treat the cases by Dr. Rochester's plan, if that is the best one. If it is not the best one, then Dr. Rochester perhaps has not the right to treat his cases by the opium method, or to say in the presence of hearers that that is his plan. It is too late a day for any one to base his practice in acute appendicitis upon impressions or personal observations that differ from the classified knowledge upon the subject. It is justifiable only when one can amass data of sufficient importance to change some classified point. If Dr. Rochester is to treat his acute appendicitis cases by the opium plan he must first give us the records of the cases that he has followed. We are to have a statement of the number of cases treated, of the proportion of deaths, of the comparative length of time wasted in bed, of the condition of the patient's general health after subsidence of the acute attack, of the condition of the appendix as determined by accurate palpation. Dr. Rochester is in duty bound to give us extremely accurate data upon these points, because human life is directly at stake, human happiness is directly at stake. If the rest of us are treating our acute appendicitis cases in the wrong way we wish to know it as soon as possible. If Dr. Rochester is treating his acute appendicitis cases in the wrong way he should know it as soon as possible. Patients trust Dr. Rochester. They trust the rest of us. The trust of numerous patients is violated.

ROBERT T. MORRIS, M.D.

November 8, 1899.

## PHYSICIAN'S ARREST ON FALSE CHARGES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In looking over last week's MEDICAL RECORD I could not help noticing your article on the unpardonable indignities inflicted upon Drs. Purdy and Maier. The reason I write you this is to narrate to you something of a similar nature, which happened to me about ten months ago, and also to comment on the gross injustice of the present law, which allows some over-zealous official to arrest on suspicion or the slightest pretext any physician who may have had some innocent connection with the case. In the early part of the present year I was called to attend a young woman aged twenty-two, who was suffering from hysteria. After several treatments she told me she was three months pregnant, and had had a slight show; she also declared that she was suffering from blood poison, which she said was due to the fœtus remaining after a flow had appeared. As she was in normal health I told her so, but this did not satisfy her, and I then told her either to get another physician or call in a reputable consultant. This was done, and the consulting physician agreed with me that, outside of her hysterical condition, she was in perfect health. This did not satisfy her, and she kept asking me to bring on an abortion. As soon as I saw what her purpose was I dropped the case, after warning her of the danger to her life if she persisted in her desires to rid herself of her child. She merely answered that she could get a certain doctor to do it any time she wanted.

This fellow was called in, and on being advised of her desires performed an operation and removed the fœtus. A week after the operation was performed the woman had an hysterical attack, and the scoundrel who performed the operation, thinking that she was in a dying condition, called in a disreputable lawyer and had a statement drawn up saying that I was the party who performed the abortion, and demanding my immediate arrest.

This document was taken to the police station, and forthwith my house was surrounded by almost the entire police force, headed by the captain and detectives. I was unceremoniously hustled to the lock-up, and kept there all night. In court the next morning I was released on bail, after being admonished by the detective to say nothing to reporters. This same detective had, I found out, later taken a reporter to the fellow who made the charge, and, together with the lawyer who was implicated with this criminal abortionist, they concocted a long story making all sorts of charges against me. After trial I was discharged. I have since then made ineffectual efforts to have the guilty parties indicted, but have met with nothing but rebuffs, being told that the parties had covered themselves in such a way that the law could not get at them. Is this justice? Why do not the authorities arrest the large number of professional abortionists who advertise their nefarious practices in the public press? Let a law be passed to make all public officials responsible for their acts; then possibly some protection might be afforded to our already suffering brothers.

WILLIAM I. LOUIS, M.D.

BROOKLYN HILLS, LONG ISLAND.

## MORPHINISM AND THE MEDICAL PROFESSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of November 4th is an editorial on "Morphinism, Drink, and the Medical Profession." You lay the fact that ten per cent. of the medical profession use morphine to the severe trials they undergo, and the excessive mental strain that they are so often placed under. Would it not be more rational to lay it to their constant association with it? All physicians carry morphine and a hypodermic syringe. They use it constantly and see its magic qualities; and regardless of the sad examples they see around them, if they are suffering from any pain or from insomnia they have more temptation to resort to the seductive drug than one who scarcely knows what a hypodermic syringe is. A bartender sees daily examples of the results of alcohol, but being in so favorable a position to obtain it he almost invariably becomes addicted to its use, and from the same cause. It is natural to place too much confidence in one's resisting-power, and to become too familiar with drugs, as with any other danger, by constant association with them.

"Vice is a monster of so frightful mien,
As to be hated needs but to be seen,
But seen too oft, familiar with her face,
We first endure, then pity, then embrace."

ALBERT S. PAYNE, M.D.

MANISTEE, MICH., November 8, 1899.

**Cremation in Germany.**—It is said that the adherents of cremation are rapidly increasing in Germany. Recent statistics place the number of cremation societies in the German empire at thirty-seven, with an aggregate membership of thirty-seven thousand six hundred, an increase of membership of more than twenty-five thousand since the beginning of last year.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 11, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 172 | 148 |
| Typhoid fever | 56 | 17 |
| Scarlet fever | 109 | 6 |
| Smallpox | 1 | 0 |
| Measles | 262 | 10 |
| Diphtheria | 248 | 37 |
| Laryngeal diphtheria (croup) | 11 | 4 |
| Cerebro-spinal meningitis | 0 | 9 |
| Chicken-pox | 15 | 0 |

**Is Alcoholism a Disease or Vice, or Both?**—Dr. J. F. Sutherland, speaking at the meeting of the British Medical Association on the drink question, touches on the above side of the evil, and says: "It is far from my intention to enter upon the fruitless task of attempting to determine whether the chronic inebriety which I am anxious to see restrained is a disease or vice, or both, further than to say that in those cases where the evidences of vice are strong, the vice if long indulged in leads in all cases to disease, even if to ordinary as well as to extraordinary observers the nervous and other systems do not present distinct evidence of degeneration, and in a large number of cases to mental and bodily change. You see I have said nothing about the part biology, heredity, and diseases present before the habit has been acquired play in the rôle of inebriety. In these aspects there is not only room for differences of opinion, but inconsiderable doubt. My case is strong enough without their aid; and the views I have just put forward will, I think, meet with the acceptance of all reasonable men, whether lay or medical."

**Plague Microbes Brought Back to Paris.**—The *English Pharmaceutical Journal* has the following amusing story: When Dr. Albert Calmette, director of the Pasteur Institute at Lille, returned from fighting the plague at Oporto a day or two ago, he drove straight to the *Figaro* office to shake hands with his brother, M. Gaston Calmette, before leaving Paris for Lille. He was welcomed by several journalists who happened to be present, among them M. Emmanuel Arène, who gives a description of the scene in the *Éclair*. Dr. Calmette had left his luggage downstairs on a cab, but he carried in his hand a little tin box which he put down carefully on the mantelpiece. Conversation became general. The doctor declared that all his experiments had been most successful. "So you know exactly what kind of plague you had to deal with?" asked one of the company. "Of course I do," was the startling reply, "for I have brought it back with me"; and the doctor calmly took the tin box off the mantelpiece, and, somewhat to the horror of his listeners, began to open it. He took out a little glass tube hermetically sealed, which contained something that looked very much like clear glycerin. There were millions of microbes in it, though they were not very easy to see. "You have only to dip a pin in this, and prick yourself," he said, "and in ten hours you would have the plague; in five days you would be dead. But you had better take my word for it," he added, smiling; and every one cheerfully did.

**Dangers of Tinned Meat.**—At the present time, when the armies of the American and the British in the Philippines and South Africa are consuming large

quantities of edibles put up in this form, the subject is a peculiarly appropriate one. *The British Food Journal* for September, treating the question editorially, concludes thus: "In Holland some two or three years ago, in consequence partly of the fact that after eating tinned food about seventy soldiers were attacked by severe illness at the Dutch manœuvres, the attention of the government was drawn to the matter by Drs. Van Hamel, Roos, and Hanneus, who advocated the use of enamel for coating tins. It appears that an enamel of special manufacture is now extensively used in Holland by the manufacturers of the better qualities of tinned food, and that the use of such enamelled tins is insisted upon for naval and military stores. This is a course which might with great advantage be followed in this country. While absolute safety may not be attainable, adequate steps should be taken to prevent the use of damaged, inferior, or improper materials, to enforce cleanliness, and to insure the adoption of some better system of canning."

**The British Medical and Nursing Department in South Africa.**—The *English Sanitary Record* says: "There is little fear regarding the medical and nursing department in the present war in the Transvaal. Half a century ago it may be said that both were nonexistent. Some rudimentary efforts toward a medical service had been made prior to the Crimean war, but the army medical corps as we now know it practically takes its date from that time, and it was in the Crimean war that the army nursing service—with which the name of Florence Nightingale is imperishably associated—also had its origin. . . . At the present day both departments are in an excellent state of efficiency, and the nursing service in particular has never been more highly organized than now. Naturally the training is extremely specialized. Before a lady can obtain admission to the service she must have passed through a preliminary period of general training in one of the recognized hospitals for at least three years; and this is followed by a further course of military nursing at Netley, the only school in the kingdom where military nursing is taught."

**To Avoid Nausea and Vomiting Following Anæsthesia.**—Blumfield makes the following recommendations: (1) To use as little of the anæsthetic as possible consistent with perfect anæsthesia; (2) to wash out the stomach at the close of the operation, when much mucus has been swallowed; (3) in protracted operations to substitute chloroform for ether after three-quarters of an hour; (4) to move the patient about as little as possible during and after the operation; (5) to place him on his right side in bed, with the head only slightly raised; (6) to give nothing but hot, thin liquid in small quantity for at least eight hours afterward; (7) to avoid altering the temperature of the room for several hours.—*The Lancet*, September 23, 1899.

**Poisoning from Canned Meat.**—Instances of poisoning from the eating of canned meats have become quite common. Although it may be possible that in some instances the ill effects arise from metallic poisoning, in a great majority of cases the poisonous substances are formed by putrefactive changes. In many cases it is probable that decomposition begins after the can has been opened by the consumer; in others the canning is imperfectly done, and putrefaction is far advanced before the food reaches the consumer. In still other instances the meat may have been taken from diseased animals, or it may have undergone putrefactive changes before the canning. It should always be remembered that canned meat is especially liable to putrefactive changes after the can has been opened, and when the contents of the open can are not consumed at once the remainder should be kept in a cold place or thrown away. People are especially careless on this point. While every one knows that fresh meat should be kept in a cold place during the summer, an open can of meat is often allowed to stand at summer temperature and its contents are eaten hours after the can has been opened. This is not safe, and has caused several outbreaks of meat poisoning that have come under the observation of the writer.—Dr. Victor Vaughan, *in Appleton's Popular Science Monthly*.

**Care of the Body After Death.**—It is ordinarily advisable that the cadavers of patients who have died of the most dangerous communicable diseases be at once enveloped in a sheet saturated with either five-per-cent. carbolic acid, four-per-cent. chloride of lime, or 1 : 1,000 solution of corrosive sublimate, and placed at once in the coffin in which each is to be buried. These cadavers should be buried as soon as decency permits. The law should, and usually does, forbid public funerals in these cases. With the less dangerous infectious diseases, however, such stringent measures are not observed. The body after death may be washed in either of the strong disinfecting solutions mentioned, though because of their odor the carbolic acid and chloride of lime solutions usually give way to the sublimate solution. It is not advisable, even in the milder infective cases, to expose the remains in open caskets. The body should be buried or cremated; the result of the two processes of final disposal differing, as a rule, only in the time required for their accomplishment. If buried the place selected should be so located as to not endanger neighboring water supplies.—"The Hygiene of Transmissible Diseases," by A. C. Abbott, M.D.

**Syphilis After Vaccination.**—Mr. Jonathan Hutchinson, in his *Archives of Surgery* for July, speaking of cases of syphilis recorded after vaccination, says: "It is now twenty-eight years since the two series of cases occurred which drew so much attention to the subject of vaccinal syphilis. About the same time several other isolated cases of undoubted character were recorded. Before these events almost the entire British profession had been incredulous as to the possibility of transmitting syphilis by vaccination. Some series, however few in number but quite as conclusive, had been recorded on the continent. These, supported as they were by our English experience, led to a prompt and universal acceptance of the belief that such transmission was a thing to be feared, and very probably to greatly increased precautions. It is now a matter of the deepest interest and a cause of great congratulation, that despite the vigilance of anti-vaccinators and their zeal in dragging such cases to the light, no considerable series of cases have been recorded. A few—a very few—isolated cases have undoubtedly occurred. The protracted inquiry of the vaccination commission did not discover more than three such, and in only one of these did more than a single infant suffer. At the same time it exposed the fallacies which underlay the diagnosis in several cases which had been certified as syphilis, but were not so."

**Trained Nurses the Best.**—A daughter of the Earl of Dufferin, late governor-general of Canada and viceroy of India, is training as a nurse in the London Hospital. Lord Dufferin inherits much of the wit and eloquence of his ancestor Richard Brinsley Sheridan, one of the greatest orators that that land of orators, Ireland, ever produced. When speaking recently on nursing, at some hospital function, Lord Dufferin, dwelling upon the necessity of a thorough training to fit a woman for nursing, made some amusing remarks on the incompetence of amateur nurses, who, however willing they might be, generally rendered the life of the unhappy patient miserable. He concluded by

saying that, although he was well aware of the fact that if he was ill his wife would do all in her power to relieve his sufferings, nevertheless he would much prefer the trained services of his daughter the nurse.

**Starch Digestion in Infants.**—It has long been the custom to say that no amylaceous substances should enter into a young infant's food because it has from nature at an early age no ferment capable of digesting starch. The saliva of a newly born child—and it is wrong to say that there is no saliva at this age—will dextrinize starch, as any one who wishes may prove for himself.—A. Jacobi.

**Good Effects of Singing.**—From the medical standpoint singing is a most important exercise both by virtue of its influence on the emotions, on the respiratory movements, and on the development of the lungs. Nothing better shows the beneficial effect of singing in developing the chest and warding off lung diseases than the great pulmonary development and freedom from pulmonary disease among professional singers. Their general health, moreover, is exceptionally good, and this is probably in a large measure attributable to the mere exercise of their calling. Such therapeutic importance do I attach to singing that I recommend it whenever opportunity affords. It is especially useful in defective chest development and in chronic heart disease. Provided the patient can sing with comfort I know of no condition in which singing is contraindicated, unless it be a tendency to tuberculous or aneurismal hæmoptysis. It is scarcely necessary to say that the singer should be so clad as to allow absolute freedom of the chest movements, there should be no constriction of the neck or waist, the collar should be low and ample, and the stays if worn ample and loose. —Dr. Harry Campbell.

**Ethics of the Profession.**—As far as can be gathered without the aid of a court trial or a grand jury, the trouble between the doctor and lawyer living about twelve feet apart in one of the best sections of the city was brought about by the children. The professional men were at first politely distant, then ceased to speak, and finally forbade their respective families to have anything to do with each other. One evening the doctor heard loud lamentations, and rushed out to find the lawyer's boy picking himself up after having scorched into the rear end of an ice-wagon and partially scalped himself. The doctor deftly made the necessary repairs, gave the lad a free lecture on looking where he was going, and sent him home. The very next month the lawyer received a bill for professional services from his neighbor. He thought unspeakable things, but sent a check. Some time after the doctor rushed excitedly into the lawyer's office. "I want to know," he shouted, "how I am going to keep those pesky kids of yours out of my yard? They're an unspeakable nuisance, and I won't stand it." "Tell their mother, and she'll attend to it. Just a moment"—as the doctor was about to hurry away. The lawyer wrote hurriedly and handed a bill for $5 legal services. The doctor fumbled in his pockets. The lawyer tried in vain not to laugh. Then the doctor laughed. The two voted themselves a pair of old fools, and shook hands. Now the children have suddenly become a mutual source of pleasure.—*New York Tribune*, from *Detroit Free Press*.

**War against Rats in Denmark.**—The London *News* says: "We hear that in Denmark a campaign against rats is being prosecuted with vigor. It was originally started in Copenhagen, where the alarming multiplication of the rats induced the municipal authorities to resort to a mediæval method (perhaps we should even say a prehistoric method) of freeing the community of beasts of prey. As a price was once offered for every head of a wolf, so the conscript fathers of the Danish capital engaged to pay a certain sum for each dead rat. An official report of the statistics of rat slaughter has been issued every week since the opening of the campaign. In the first week the rat-catchers, professionals and amateurs, gave in the heads of 6,000 rats, in the second week 6,616, in the third week 6,780. We are told that the average weekly bill of mortality among the rat population of Copenhagen has now risen to about 10,000. Other towns and communes followed the example of the capital, and the Danes are making a patriotic attempt to exterminate 'the petty wolf,' as Hendrik not inaptly named the rat."

**Zacharin as a Teacher.**—Dr. Rovinsky, in his introduction to the volume of clinical lectures by Zacharin just published says of Zacharin that he was connected in the capacity of instructor and professor with the medical department of the Imperial Moscow University for a period extending over thirty five years. A man of indomitable energy and very pronounced individuality, he is considered as the founder of what is known in the Russian medical world as the Zacharin school of practical medicine in whose tenets were brought up several generations of physicians scattered in every nook and corner of the great empire. He came of a poor but very old family of nobility, and was compelled from his early student days to struggle with want and privation, but, thanks to the possession of an iron will and unswerving determination, he rose to a position equal to that occupied by Botkin and Pirogoff. It may be truly said that Pirogoff, Botkin, and Zacharin form the great triad of Russian clinical medicine of the nineteenth century.

**University for Women in Russia.**—Russia, although perhaps, with the exception of Turkey, the most backward of European countries, is now making strenuous efforts to catch up with the more advanced nations. The freeing of the serfs was the first great step in this direction. In matters medical especially has she bestirred herself within the past thirty years. The position of the medical man in Russia was one of almost ignominy no longer than thirty years ago. He was looked upon as a servant, and was not even permitted to seat himself in the presence of those of higher rank who might require his professional services. All that has been changed, however, thanks greatly to the labors of such men as Botkin and Zacharin, and at the present time the Russian physician takes his proper position as an educated man. The visitors to the International Medical Congress in Moscow were astonished at the high state of excellence to which the hospitals and medical schools had been brought, and it may be said without exaggeration that, with regard to its professors and to the means afforded for scientific research, St. Petersburg and Moscow need fear comparison with no large city in the civilized world. To prove that this forward movement shows no signs of retrogression, the news has recently come that a university for women is to be founded in Moscow. A wealthy Russian has left $500,000 for that purpose, and the municipal council of Moscow has supplemented this bequest with an annual grant of $1,500.

**Danger to Health on Board Passenger Steamers.**—Dr. Anderson contributes an article with the above title to the *Journal of Tropical Medicine*. He classifies the dangers as follows: Class A—Contagion from (1) tuberculous fellow-passengers or those affected with dermatitis; (2) want of proper hospitalization of sick passengers and sailors; (3) inadequate accommodation for troops invalided home; (4) water-closet leakage; (5) cattle-pens and menageries; (6) water-closets

on the lower decks; (7) desiccated sputum on deck; (8) impure water taken on board at ports of call; (9) food and drink partaken of ashore; (10) miasma in harbor; (11) mosquito bites. Class B—Danger from imperfect ventilation. Class C—Danger from unsuitable cabins. Class D—Danger from the heat and from exposure to the sun's and moon's rays in the tropics and in the torrid zone. Class E—Danger from want of exercise. Class F—Danger from uncontrolled medication. Class G—Danger at the hands of inexperienced medical officers.

**How Brain-Workers Should Eat.**—It is all right, says a writer in the *Sanitary Record*, for the man who labors all day in the open air to eat freely; but the man of sedentary habits, the brain-worker, must adapt his way of living to his needs. He must be well nourished, for the brain is incapable of good work unless well supplied with pure blood, but such a man cannot possibly furnish vital force to digest three large meals daily. If he tries it, nature will protest at every step. The chemical changes of digestion will be imperfectly performed. The stomach will neither secrete freely nor churn the food with cheerful alacrity; the pyloric orifice contracts and allows such chyme to pass with grudging reluctance; the intestinal lacteals are ashamed to absorb such miserable pabulum, which chokes, irritates, and congests them, so the large meal remains in the digestive organs to ferment, putrefy, and steep the individual in foul gases and depraved secretions. But the system can furnish enough vital force to convert a small meal into pabulum of high standard, which will be absorbed without difficulty. Three such small meals are not enough to keep the individual properly nourished, however; four to six will be required. Each should consist of but one or at most two articles of food, the diet to be varied by changes at meals. The portion of food served must be small; the patient must stop as soon as the appetite is satisfied, and gaseous distention is proof positive that the meals are still too large or too close together.

**The Prophylaxis of Malaria; the War against Mosquitoes.**—Since the part played by mosquitoes in the transmission of marsh fevers has come to be known, many scientists have occupied themselves with the question of the measures to be taken against these insects. These measures may be divided into two classes: measures which have as their end the destruction of the mosquitoes *en masse*, and those whose object is to protect individuals from their bites. The measures advocated to destroy these insects are numerous. They comprise all the possible ways of abolishing marshes and ponds by drainage and forming plantations (principally of pine and eucalyptus). The keeping in motion of the water of pools during summer by means of water-wheels moved by small windmills (Howard) appears to be an excellent method; it has been used at San Diego in Texas. Parks or garden ought not to be made; they are nothing but receptacles for mosquitoes. As a measure against the larvæ of the pathogenic insects, the reasonable plan has been suggested of pouring into the water of the ponds common oil, or, better still, petroleum. Twenty-two litres of oil are sufficient to cover efficaciously a surface of ninety-six thousand square feet. It is important to pour in the oil at the beginning of the hot season (Howard, Smith, Weed, Kelley, Nuttall). Petroleum oil of weak consistency has no influence on the lives of the fish. Sulphate of iron and permanganate of potash, both of them highly praised, do not give results so satisfactory as those produced by oil. Fish are good auxiliaries in the destruction of the larvæ (Russell), hence the necessity of favoring pisciculture in malarious countries; the three-spined stickleback (Gasterosteous aculeatus) is especially recommended (Howard). Within the last few years particular insects (mosquito-hawks) have been employed in America to destroy mosquitoes. One of the questions to which the inhabitant of a malarious country should devote special attention is that of the choice of dwelling. He should build his house always on the hills or in elevated spots; inhabit the upper stories of his house; keep away from gardens and ponds; plant round his house trees of Eucalyptus globulus, or, better still, of the Ricinus communis (Giard); use petroleum lamps and keep them lighted in the room that communicates with his bedroom. To free a room from the mosquitoes it may contain the best process consists in burning pyrethrum (Campbell); the mosquitoes fall down and die. Howard's advice is to moisten the powder of pyrethrum, make balls of it, dry them, and burn one or two as the case may be. According to Weeder, the leaves of Mentha pulegium keep away mosquitoes. Eator, to the same end, advises putting a branch of eucalyptus under the pillow. Weed attributes more effect to daily anointing the face and hands with petroleum oil. In Canada a mixture of tar and oil or camphorated vaseline is used in the same manner. The Hudson's Bay Company recommends tar water for the skins of both men and animals. At Imibirsk excellent effects were obtained by the use of a strong infusion of roots of Triticum repens (Beutenmüller). Chappel has quite recently recommended infusion of quassia. Pednoff is emphatically in favor of naphthalin dissolved to saturation point in liquid vaseline.—*English Veterinary Journal*, translated from *Revue Scientifique*.

**The Origin of the Decimal System.**—The decimal system, it has been said, was evolved from the human hands, which with their ten fingers constituted the only counting-board used by primitive man. It is well known that the system was not perfected until ciphers were introduced. This cipher system was invented in India in the fifth century, and its introduction into Europe is generally credited to Leonardo Fibronacci, better known as Leonardo Pisano, the author of "Liber Abaci," published in 1202. Leonardo learned the Arabian tongue and art of reckoning from his father, who lived in the Arabic city of Bugia. But before Pisano's time, another "Liber Abaci" had been written by Gerbert, which is based on a cipher system. At the last Toulouse Congress, R. Astier showed that the same system had already been employed in the "Geometria" of Boethius, in the sixth century, and hence long before the introduction of Arabic signs into Europe. Astier states that the counting board (abacus) of the Greeks and Romans, which serves as the basis of column reckoning, was invented by the Babylonians, who, it will be remembered, are usually thought to have used only the duodecimal system. Astier supports his assertion by citing an old abacus which seems to have escaped the attention of such mathematical historians as Chasles, Montucla, Marie, Bossut, as well as the old lexicographers Rich and Saglio. The precious document in which the abacus is described has been preserved by a Renaissance scholar, Balsani (Pierins Valerianus) in his work, "De Sacris Ægyptorium Literis." The system which he describes contains nine numbers, running from one to nine, a cipher or zero being dispensed with by using a special column, and a decimal arrangement of figures progressing from left to right. The numerical characters of this abacus of Balsani's are in every way similar to the cuneiform letters of the Chaldeans, and entirely different from Arabic numbers. Balsani's abacus would, therefore, lead us back to Babylonian days; and the period or comma which plays

so important a part in the decimal system is really a cuneiform character. Astier has requested Assyriologists carefully to examine the statue of a builder in the Louvre, usually designated as the statue of King Gudea (2500 B.C). It is generally supposed that Gudea is here represented as a builder holding in his hands rule and compass, and on his knees a rectangular tablet on which the scale of Babylonian measurements of length are inscribed, together with a figure which has hitherto been considered the plan of the building. Astier holds that this scale is perhaps a Babylonian abacus, and King Gudea is represented as the inventor of the decimal system. So bold an hypothesis can be accepted only after a most searching investigation on the part of Assyriologists.—PROMETHEUS, in *American Druggist and Pharmaceutical Record.*

**Triplets.**—Dr. R. E. Hyde, of Beekmantown, N. Y., writes: "I was called on the night of September 21, 1899, to attend Mrs. A. A. Jubar, aged thirty-nine years, the mother of nine children. I found her in the second stage of labor. In about an hour she gave birth to a child; in twenty minutes another child presented feet first; and in less than twenty minutes more another came with a head presentation. All three were born in less than one-half hour. All were girls and their total weight was seventeen and a half pounds. There were three cords, three sacs, and one placenta. At the time of writing, five weeks after birth, all the children are well."

**A Slump in Operations.**—A veritable slump has occurred in this department during the past few years. When adenoids first came out the operation value was often quoted at 52½; then there was a drop to 31½; then to 26¼. In the present day the price is generally about 15¾, and when business is dull it may even fall to 10½. Again with abdominal operations, the proper market price of these stands at 105; at least it ought to stand at that figure, but the amount of fluctuation which takes place in this stock is, as far as I hear, heartrending. The price has been known to drop to 21 quite independently of international complications with Mr. Oom Paul. As for amputations, now seldom heard of, their price has ceased to be quoted at all. As a matter of fact, it would seem that the more the public are provided with skilled medical assistance, the less they will pay for it. The only way, therefore, of saving the situation is to increase the output of millionaires.—*West London Medical Journal.*

**The Visions of the Black Man.**—Miss Mary H. Kingsley, daughter of the late well-known author, the Rev. Charles Kingsley, has been giving some of her experiences in West Africa, where she travelled on an exploring and scientific expedition for some months. Speaking on the subject of the black man's proneness for seeing apparitions she says: "I have had an extensive and sad experience with people—white and black, strong-minded and weak-minded, educated and uneducated—suffering from delirium, which has taught me that men under certain physical conditions can and do see things that men in a normal state cannot and do not see. I also know that the African, in spite of all his hard common sense, is endowed with a supersensitive nervous organization; he is always a step nearer delirium in a medical sense than an Englishman. A disease that will by rise of bodily temperature merely give an Englishman a headache will give an African delirium and its visions. Whether this indicates a difference in physical make between Africans and Englishmen I do not know. It may be that the African, by his long process of acclimatization to malarial districts, has a chronic state of malarial delirium; or, on the other hand, it may be that his undoubtedly more sensitive nervous system enables him to see things the duller-nerved Englishman does not; or one might say the African mind may be a more perfect photographic plate on which the spirit-world can print itself."

**Causes of Constipation.**—(1) Those springing from the violation of hygienic law; (2) defective innervation, expressed either in atonicity of the muscular coats of the intestine or in decreased secretion; (3) sluggishness of the bowel function; (4) the habitual use of purgative medicine; (5) mechanical obstruction; (6) painful affections of the anus.—A. B. COOK.

**Medical Volunteers.**—A good word for the American medical volunteers is spoken by the *British Medical Journal* of September 23d, in its notice of the report of the medical work of the Massachusetts Volunteer Aid Association during the Spanish war. "The American people," it says, "with all their practical ability and unlimited resources, no more than others can successfully carry on war with an improvised army without the aid of such private enterprise. The ship fitted out by the committee was so complete that she may be looked upon as a model for future ships of the kind."

**Beer Drinking.**—Recent statistics show that the consumption of beer in Germany during the year 1897-98 was 1,383,700,000 gallons; 1,192,000,000 in Great Britain; 180,000,000 in France, and about 90,000,000 in Russia. A better notion of the popularity of beer as a beverage is to be had from the estimates of consumption "per head" of the population. It is reckoned at 36 gallons in Belgium, 32 in Great Britain, 25 in Germany, 21 in Denmark, 12 in Switzerland, 10 in the United States, 9½ in Austria-Hungary, 9 in Holland, 5 in France, 3½ in Norway, 2½ in Sweden, and 1 in Russia.

**Modern Treatment of Insanity.**—*The London Hospital*, in an article on insanity, concludes thus: "In the closing decade of our century we are standing on the threshold of a new epoch in which insanities are beginning to be studied and investigated as other diseases; progress, steadily but surely, is making its way in the growth of knowledge regarding etiology, hereditary conditions, pathology, and therapeutics; the brain as the affected organ and every other part of the body as partners in the morbid manifestations which in their totality we call insanity are receiving examination with all the wealth of methods and means that modern science supplies; statistical and sociological studies are contributing their quota toward the elucidation of the problem, and the closing years of the century are full of promise and hope for the future. Perhaps the time is not far distant when by intelligent social and legislative measures, by the growth of an enlightened public opinion, and by the spread and diffusion of medical and scientific knowledge, much more may yet be accomplished toward the treatment and prevention of the insanities. Suffice it, however, for the present century that it has completed the humanitarian epoch, and inaugurated the scientific."

**Causation of Night Terrors in Children.**—Dr. G. Graham Little read a paper before the British Medical Association on the above subject, and drew the following deductions from the cases which had come under his notice: (1) Night terrors are in the great majority of cases caused by disorders productive of moderate but prolonged dyspnœa. (2) A preponderating number of cases are found in rheumatic subjects with early heart disease. (3) A considerable proportion

of cases are due to obstruction of nasal cavities and fauces. (4) Digestive disturbances do not play the important part in causation that is often assigned to them. (5) The evidence for their causal connection with epilepsy or allied neurosis is scanty. (6) The attacks occur in the subconscious stage of early sleep, and are confined to children under puberty.

**Starvation in London.**—London, although the richest city in the world, supplies quite her fair share of deaths due to starvation. It is gathered from a parliamentary return recently issued with respect to the number of deaths in London from starvation, or accelerated by privation, that the total number of such cases was forty-eight. In the Eastern District there were fifteen deaths from this cause, in the Northeastern thirteen. These, by the way, are only the cases of death from unexplained causes which come before a coroner. Doubtless there are many others which are never known.

**Magiphonia.**—Owing to a lack of tension of the vocal cords, singers or speakers may notice that singing or forced or accentuated speaking may become at first difficult and finally impossible. The cords employed in ordinary conversation, without the added burden of increased effort, as in singing or loud declamation, respond normally. The condition is known as magiphonia, and is analogous to other occupation neuroses, such as writer's cramp, etc. The affection may simulate either the tremulous or paralytic variety of this disease, the latter form, according to Fränkel, being the more important. Massage and friction give best results in the treatment.—"Diseases of Nose and Throat," by DR. D. BRADEN KYLE.

**Wine Cheating.**—A correspondent of the London *Globe*, says the *British Food Journal*, in approving of the activity of food-inspectors and others in detecting frauds on the public, refers to some cheats which have been attempted upon himself and are presumably part of an extensively practised system. On one occasion at a restaurant he ordered à particular brand of port. On tasting the wine served to him, he discovered that it was not what he asked for, and after repeated denials the cellar-man had to confess that, being out of the wine, another had been substituted. A similar deception occurred with reference to a celebrated brand of claret, for which apparently some draught wine had been substituted. The cellar-boy admitted, on being reproached for the delay, that they had no Chateau bottled.

**Bacilli and Blackmail.**—According to a Vienna correspondent a blackmailing case with a humorous aspect has been occupying the attention of the criminal courts at Gratz. An elderly lady of great wealth one day received a letter saying that if she did not send the sum of 10,000 florins in small bank notes the writer would work a fearful revenge by opening in her room a bottle containing the bacilli of various infectious diseases, which would certainly cause her death. The lady appealed to the police, who discovered the would-be blackmailer. A bottle found in his possession really contained bacilli, which the culprit, who is a medical student, had stolen from his professor's lecture room. A sentence of eighteen months' hard labor will doubtless prevent this promising youth from further blackmailing enterprises.

**Tetanus.**—The statement is published that M. Nocard has distributed a large quantity of anti-tetanic serum which has been used for injection into various animals as a prophylactic against tetanus. He asserts that out of twenty-three hundred beasts so injected not one suffered lockjaw after operation. So far good, but we should like to be told how many of them would probably have so suffered if they had never been injected.—*Medical Press.*

**Brachycephalism** was the affection from which a man, arrested for intoxication last week, claimed to be suffering. Magistrate Pool thought that a pretty bad disease, and let him go.

**Salt for the Morphine Habit.**—Salt, according to some authorities, is one of the most efficacious remedies in cases of morphinism, and in chronic diseases attended by impaired elimination. Three to five grains per day, followed by a draught of water, will cause the glands to work more actively, and will at the same time stimulate the mental faculties.

**Embalming Fluid.**—

| | |
|---|---|
| ℞ Crude petroleum | 1 gal. |
| Camphor | 4 lbs. |
| Carbolic acid | ½ lb. |
| Fowler's solution of arsenic | 1 lb. |

M. S. Extract the blood from the body and inject.

—MARK L. NARDYZ.

**Sanatorium in the Egyptian Desert.**—*The London Hospital* says: "It will be good news to many consumptive invalids to learn that a large sanatorium for consumptives will be open, probably in November, at Helonau in Egypt. The building will be open to the desert on all sides, and the roof will be utilized as a winter garden. The window casements are to be constructed for the unrestricted admission of air. Separate rooms with bath-rooms are to be provided, and about seventy patients will be accommodated."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 11, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **SMALLPOX—UNITED STATES.** | | | |
| Illinois, Chicago | October 27th to November 4th | 1 | |
| Iowa, Ottumwa | October 1st to 7th | 1 | |

### A REVIEW OF THE HISTORY AND LITERATURE OF APPENDICITIS.

BY GEORGE M. EDEBOHLS, A.M., M.D.,

NEW YORK.

DURING the early part of the present year the writer had occasion to look up one or two points in connection with the subject of appendicitis. He became interested and more and more deeply involved in the literature, until after a number of months, during which all his spare moments were devoted to the task, he found that he had read and passed in review about all that has ever been written upon appendicitis. The magnitude of the labor becomes apparent when it is stated that the literature of appendicitis, up to and inclusive of the year 1898, embraces more than twenty-five hundred journal articles, dissertations, and books, all but a very small fractional part of which the writer has consulted in the original. As illustrating the rapid growth of the literature it may be stated that more than one-half of the twenty-five hundred journal articles, dissertations, and books have appeared within the past five years.

Upon the conclusion of the task, and at the suggestion of the editor of the MEDICAL RECORD, who thought that a historical review of the subject of appendicitis might interest some of the readers of his journal, the following notes were arranged for publication.

**Nomenclature.**—Epityphlitis, ecphyaditis, and scolecoiditis have been proposed by Kuester, Morris, and Gerster, respectively, as synonyms for appendicitis. The term appendicitis, however, though a barbarism, is too firmly established by long and universal usage, both among the profession and the laity, to be displaced at this late day. We bow to the inevitable, and, for reasons which have been well set forth by Ellis,[109] accept the term appendicitis.

**General Historical Data.**—The early history of appendicitis is merged with and emerges from that of iliac phlegmon, typhlitis, paratyphlitis, and perityphlitis. Saracenus, in a letter dated August 28, 1642, published by Roussel,[304] describes an abscess in the right iliac region with discharge of fecal matter and fourteen lumbricoid worms, possibly the most ancient clear case of perityphlitic or appendicular abscess on record. A number of similar cases were published during more than a hundred years following, before Mestivier,[234] in 1759, recognized appendicitis as a distinct entity. Mestivier incised an abscess in the right groin, in a woman far advanced in pregnancy, and on autopsy found at the bottom of the abscess the appendix vermiformis perforated by a pin. Toward the end of the eighteenth and during the early half of the nineteeth century, appendicitis with perforation and abscess formation was often found in the dead-house and described by numerous writers. Yet, as late as 1838, so learned a man as Albers,[7] writing at length on typhlitis and perityphlitis, does not even mention the appendix—proof that a knowledge of the existence of appendicitis was by no means general at that time. The complications and sequelæ of appendicitis, especially those fatal in character, were also noted during the early half of the present century. In 1846 Landsberg[191] reported two cases of hernia, one inguinal and one femoral, containing the appendix. Hall,[143] Zdekauer,[325] Monks,[236] Ohlmacher,[208] Pollosson,[277] Rotter,[303] Routier,[305] Kayser,[171] Ginnard,[110] and Gross[138] have since reported like experiences. In 1847 the diagnosis of appendicitis began to be made during life by Cless,[61] Hancock,[146] and others. In the fifties Cless,[62] Bamberger,[14] and Leudet[201] reported large numbers of personal observations of perforative appendicitis with autopsies; Leudet, for example, reporting thirteen cases of perforation and seventeen cases of simple ulceration of the appendix observed by him in three years. Skoda,[324] in 1862, noted the spontaneous cure of appendicitis by obliteration, and advises a "hardening process" treatment with that end in view. With,[367] in 1879, fully described peritonitis appendicularis, and Bierhoff,[34] in 1880, gave an excellent, full, and elaborate description of the pathology of appendicitis, modern in every respect except as to bacteriology. The classic of Fitz,[116] which appeared in 1886, may fairly be said to have given the impetus to the intense and practical study of appendicitis of latter years.

The bacteriology of appendicitis first received attention in 1891, chiefly at the hands of the Frenchmen Adenot[5] and Gouillioud,[136] soon followed by Eckehorn,[106] Weir,[360] Robb,[293] Hodenpyl,[157] and others.

The diagnosis of acute appendicitis was advanced more than by all previous knowledge combined, by McBurney,[219] when, in 1889, he discovered and established the value of "McBurney's point." The introduction and elaboration, in 1894, by Edebohls,[96] of palpation of the vermiform appendix finally placed us in a position to diagnose clearly and positively every case of chronic, and nearly every case of acute, appendicitis.

The history of the origin and development of the operative treatment of perityphlitic abscess and of appendicitis will receive full attention later on under a special heading.

**Frequency of Appendicitis.**—As regards both the frequency of appendicitis and its relative frequency in the two sexes, the most remarkable and apparently irreconcilable statements are made by various investigators. While the belief is current that appendicitis affects males in larger proportion than females, Einhorn,[105] in eighteen thousand successive autopsies, found perforating appendicitis in 0.55 per cent. of males and 0.57 per cent. of females, and Robinson[294] in one hundred and twenty-eight autopsies as they came found evidences of past peritonitis on and about the appendix in sixty-six per cent. of female and fifty-six per cent. of male bodies.

With[367] quotes Toft as finding in three hundred autopsies one hundred and ninety entirely normal appendices and one hundred and ten appendices presenting more or less evidences of disease. Wallis,[356] on the contrary, in autopsies extending over nearly five years found only 1.7 per cent. of all appendices presenting evidences of disease. Fitz,[116] in 1886, reports two hundred and fifty-seven cases of perforative appendicitis observed by him post mortem, and comments

upon the frequency with which autopsy shows long-standing chronic inflammation without acute attacks. Ribbert[257] and Zuckerkandl[376] have given us post-mortem statistics of obliterating appendicitis. The former, in four hundred autopsies, found the appendix partially obliterated in 21.5 per cent. and completely obliterated in 3.5 per cent.; the latter, in two hundred and thirty-two examinations, found 9.9 per cent. of partial and 13.8 per cent. of complete inflammatory obliteration of the lumen of the appendix. Clinically, Edebohls[101] finds that four per cent. of all women have appendicitis.

**Anatomy of the Vermiform Appendix.**—According to Kelynack,[177] the existence of the appendix does not appear to have been recognized previous to the sixteenth century, when it was described by Carpi, Estienne, and Vidus Vidius, the latter of whom applied the qualifying term "vermiform." Santorini and Sabatier described it quite satisfactorily in the seventeenth century. But it is only since the appearance of the classic of Lieberkühn,[205] in 1739, and that of Vosse,[355] in 1749, that a description of the vermiform appendix has found its way into every text-book of anatomy.

Finnell,[118] in 1869, measured fifty male and fifty female appendices, and found the appendix averaged one-half inch longer in women than in men. Mott,[241] Biggs,[55] Dade,[73] and others have put on record exceptionally long appendices. The general anatomy of the appendix has received consideration at the hands of Hewson,[154] Ribbert,[257] and many others. Ribbert's macro- and microscopical examinations of four hundred appendices deserve special mention. The variations of position observed post mortem have been minutely investigated by Bryant.[50] The peritoneal folds and fossæ in the immediate neighborhood of the appendix are fully described and pictured by Lockwood and Rolleston,[209] Kelynack,[177] and Jonnesco.[165] Swan[339] records the only well-authenticated case of congenital absence of the appendix.

**Etiology of Appendicitis.**—The causative factors in the production of appendicitis are universally admitted by all writers to be very generally local in character. Fox,[93] in 1885, called attention to the analogy between quinsy and appendicitis, in both of which lymphoid tissues identical in structure were involved. Atkinson[13] and Bloomfield,[39] in 1895, discussed heredity as a cause, and "family appendicitis" was again brought forward by Faisans[111] in 1896. In 1891 Adenot[5] and Gouillioud[136] developed the important rôle played by bacteria in the etiology of appendicitis. In 1895 and 1896 quite a crop of general causes of appendicitis sprang up in the literature. Frazer[126] writes of uratic typhlitis, Matthieu[216] of *la lithiase appendiculaire*, and Simons[323] describes a case of gouty appendicitis. Rheumatism was advanced as a cause by Sutherland,[327] followed by Beverley Robinson.[290] Byron Robinson[294] finds the chief exciting cause of appendicitis in the action of the psoas muscle. La grippe is considered by a number of New York physicians of prominence and large experience a frequent cause of attacks of appendicitis. The etiology of relapses has been carefully and minutely studied by von Mayer.[353] Goluboff[145] calls appendicitis an epidemic infectious disease. Edebohls[100] has pointed out the rôle played by movable right kidney in the production of appendicitis.

**Pathology of Appendicitis.**—The general gross pathology of appendicitis has received full attention in the writings of Leudet,[201] With,[362] Bierhof,[34] Porter,[281] Fitz,[116] and numerous others. The microscopical appearances have been carefully studied by Craig,[67] Ribbert,[257] Letulle and Weinberg.[200] The spontaneous cure of appendicitis by obliteration was noted by Skoda[324] in 1862, and the cure of perforation of the appendix by the same process was recorded by Pepper[266] in 1867. Later, Senn,[315] Zuckerkandl,[376] and Piersol[270] wrote on "appendicitis obliterans," the last-named author designating it nature's cure. Catarrhal appendicitis, though generally recognized, has received but scant description, the only noteworthy contribution, perhaps, being that of Deaver.[79] The pathology of interval cases is well described and pictured by Abbe.[1] "Appendicite sous-hépatique" is considered worthy of special description by Glantenay.[139] The homology of appendicitis with salpingitis is insisted upon by Delbet.[84] A solitary case of intramural abscess of the appendix is recorded by Pilliet,[253] and a solitary observation of suppurative typhlitis with a normal appendix by Lop.[212]

**Foreign Bodies in the Appendix.**—In former years foreign bodies in the appendix were considered under the head of etiology of appendicitis. In the light of modern views the permanent lodgment of foreign bodies in the appendix is probably more frequently the result than the cause of appendicitis. In the following list, by no means complete, of foreign bodies found in the appendix, reference to publication is omitted.

Entozoa have been found in the appendix in the following varieties: Ascarides lumbricoides (Becquerel, Patterson, Lang, Buck, Cuthbertson); Oxyuris vermicularis (Bierhof); Tricocephalus dispar (Bierhof).

Coproliths have been found by everybody who has had much to do with post-mortem investigations or with the surgery of the appendix. Next to coproliths, pins have been the foreign bodies most frequently met in the appendix (Mestivier, Hewitt, Joffroy, Legg, Boussi, Ashby, Shoemaker, McPhaedran, Calmer, Vanderveer, Park).

Other foreign bodies found in the appendix are: grape seeds (Briske, Pepper, Noyes, Hebb); melon seeds (Tavignot, Malespine, Edebohls); a chocolate nut (Prescott); a grain of oat (Price, Howe); cherry stones (Theurer, Werner, Reignier, Ferguson, Formad); raspberry seeds (Vedder, Craig); prune stones (Vidal, Stuetzle); a date seed (Leaman); orange seeds (Thornton, Service); a bean (Cliquet, Haeker, Wyman); tomato seeds (Edebohls); a fruit stone (Firket); huckleberry seeds (Brundage); blackberry seeds (Vanderveer, Wilson); shell of hazelnut (Southam); a piece of chestnut (Owens, Formad); peanuts (Rosenheimer); hair (Peterson, Hildebrandt); a bristle (Ward, Gibbons, Ulloa y Geralt); a glazier's point of zinc (Bartlett); a globule of solder (Morton); a gelatin capsule (Roberts); a piece of bone (Ferguson, Coleman); a piece of screw nail (Ferguson); a rifle cartridge (Ransohoff); fin of a fish (Ashton); knot of a heavy silk ligature from a tubo-ovarian pedicle (Edebohls).

**Pathological Conditions Other than Inflammation Affecting the Vermiform Appendix.**—For the sake of completeness I append a list of various diseased conditions of the appendix other than inflammatory, which I have found recorded in the literature: Prolapse of mucous membrane of appendix (Rolleston[300]); invagination of appendix (McKidd[225]); intussusception of the appendix (McGraw,[226] Wright and Renshaw,[371] Waterhouse[357]); cystic dilatation of appendix (Gruber,[139] Shoemaker,[321] Hawkins,[81] Coats[63]); retention cyst of appendix (Maylard,[217] Sonnenburg[329]); mucocele of appendix (Féré,[114] Vimont,[345] Baillet[16]); hydrops of vermiform appendix (Combemarle,[65] Guttmann,[141] Ribbert[257]); tuberculosis of appendix (Apert[10] and numerous others); echinococcus of appendix (Bierhof,[33] Birch-Hirschfeld[37]); actinomycosis of appendix (Ekehorn,[106] Gangolph and Duplant,[127] Czerny[72]); cystic degeneration or alveolar carcinoma of appendix (Rokitansky[229]); primary colloid cancer

of appendix (Draper[90]); primary cancer of appendix (Mosse and Daunic[217]); cancer of appendix (Stimson[336]); primary adenocarcinoma of appendix (Wright[372]); primary endothelial sarcomata of appendix (Glazebrook[134]).

**Bacteriology of the Appendix.**—Clarke[57] has felicitously entitled the appendix a culture tube. Since Adenot[5] and Gouillioud,[136] in 1891, began the study of the bacteriology of the appendix and showed appendicitis to be due, in practically every case, to bacterial invasion of the appendix walls, most frequently by the bacterium coli commune, researches in this direction have been continued with uninterrupted zeal and enthusiasm by a number of workers. Ekehorn,[106] in 1892, proved that the bacterium coli manifested different degrees of virulence in different cases, and that it is present in every form of appendicitis, from the catarrhal onward. Robb,[293] in 1892, reported a case of associated streptococcus infection of the vermiform appendix and right Fallopian tube. Morris,[239] in 1893, published the first article with the distinct title, "Infectious Appendicitis." Weir,[360] in 1893, found the diplococcus pneumoniæ in nearly pure culture in the appendix in a case of purulent appendicitis, and Ohlmacher,[259] in the same year, found the proteus vulgaris. Hodenpyl,[157] in 1893, contributed a most important bacteriological study of appendicitis based upon an examination of thirty-five cases. Achard and Broca,[1] in 1897, presented a noteworthy résumé of the bacteria found in the peritoneal exudate in twenty cases of appendicitis. Beaussenat[26] has given us the most important paper on experimental appendicitis. His experiments, supplemented by those of Josué,[171] prove that germs may invade the lymphoid tissue of the appendix by way of the blood and by way of the lymphatics, as well as through the mucous membrane. Hartmann and Reymond[150] report an observation of the passage of the bacterium coli from an appendix abscess through the intact bladder wall, causing infectious cystitis.

**Complications of Appendicitis.**—The complications of appendicitis are impressive by reason of both their number and their gravity. Mortier,[241] Little,[208] Sheffey,[318] Bennett,[28] Lincoln,[206] Perry,[268] Andrews,[9] Pitres,[275] Hendricks,[158] Englisch,[110] Dale,[74] Bierhof,[33] Murray,[253] Weiss,[362] and Morris[240] have recorded cases of intestinal strangulation, the result of appendicitis. Death from hemorrhage has resulted from perforative ulceration, due to appendicitis, (*a*) of the small intestine (Osler[260]); (*b*) of the sigmoid (Stedman[333]); (*c*) of the right external iliac artery (Powell,[283] Sourdille[331]); (*d*) of the right iliac vein (Fowler,[120] Lewis[204]).

Other complications or sequelæ noted are: Prolapse of the mucous membrane of the appendix into the cæcum (Rolleston[300]); invagination of the appendix (McKidd[225]); discharge of the gangrenous appendix per rectum (Jackson,[164] Long[210]); fæcal fistula (Long,[211] Rioblanc,[292] and numerous others); appendiculo-intestinal fistula through a suppurating mesenteric gland (Packard[261]); vesico-intestinal fistula (Keen[175]); perforation of the colon, rectum, and bladder (Rochester[297]); perforation of the bladder (Clark,[56] Boardman,[40] Cameron[53]); perforation into the bladder with formation of stone (Fowler[124]); localized and general peritonitis, by almost every writer; obliteration of the right crural artery by arteritis (Bérard[29]); embolism of the left anterior tibial artery, with gangrene of the leg (Scheibenzuber[310]); embolism of the pulmonary artery (McGregor); phlebitis of the right iliac; phlebitis of the left leg (Freeman[127]); thrombosis of the right femoral vein (Legg[194]); phlebitis and thrombosis of the vena mesenterica magna and portal pylephlebitis (Aufrecht,[14] Ssawostjanow[332]); purulent inflammation of the portal vein (Baernhoff,[15] Moers,[235] Machell,[214] Mynter,[291] Carless[71]); portal pylephlebitis and hepatic abscess (Traube,[345] Pierson,[271] Davat,[79] Boussi,[42] Jorand[170]); hepatic abscess, "la foie appendiculaire" of Dieulafoy[88] (Krakowitzer,[183] Ashby,[12] De Gennes,[82] Shoemaker,[321] Harte,[148] Achard,[1] Nuding,[248] Pilliet and Costes,[272] Sheen,[317] Morton[232]); left perinephritic abscess, perforation of the diaphragm, left purulent pleuritis (Coats[63]); right perinephritic abscess, perforation of the diaphragm, right empyema (Ardouard,[11] Shiels,[319] Rioblanc[292]); the same, with perforation of the lung (Thacher[343]); the same, with gangrene of the lung (Mader[215]); right pleuro-pneumonia (Dupré[92]); subphrenic abscess (Sachs,[307] Freiberg[125]); perforation of the eighth intercostal space and right lung (McCallum,[221] McPhaedran[229]); purulent cystitis, due to migration of the bacterium coli commune through the intact bladder wall (Hartmann and Reymond[150]); prevesical abscess (Tuffier[347]); ureteritis, pyelonephritis (Hectoen[152]); scrotal abscess and purulent pleuritis (Lemariey[197]); multiple distant abscesses (Pirard[247]); glycosuria (Leidy[196]); fusion of the appendix to the gall bladder (Czerny,[72] Edebohls). Beurnier,[30] Czerny,[72] and Shoemaker[320] have devoted special attention to the coexistence of appendicitis and membranous colitis.

**Herniæ Containing the Appendix.**—The appendix has frequently been found among the contents of a hernial sac. Landsberg,[295] Hall,[143] Zdekauer,[375] Monks,[236] Ohlmacher,[259] Kayser,[174] and Gross[138] have recorded cases of inguinal hernia containing the appendix. The case of Hall is historical from the fact that it represents the first removal of the appendix with survival of the patient. Landsberg,[191] Pollosson,[277] Rotter,[303] Routier,[305] Ginnard,[140] and Vanderveer[347 b15] have found the appendix as part of the contents of a femoral hernia.

**Appendicitis Associated with Diseased Conditions of the Pelvic Organs.**—The association of an inflamed appendix with every variety of diseased conditions of the pelvic organs, more especially of women, is a matter of almost daily observation in the practice of abdominal surgery. In some cases the appendix is the starting-point of the diseased action, in others it becomes involved secondarily to disease affecting primarily the pelvic viscera. Baldy,[17] Richelot,[291] Mixter[234], Robb,[293] Jaggard,[169] Binckley,[38] McGuire,[227] and Deaver[81] have, among others, given special attention in their writings to this aspect of our subject.

**Appendicitis Complicating Pregnancy, Labor, and the Puerperal State.**—The classical case of Mestivier,[232] the first in which a diseased appendix, in this case containing a pin, was recognized at autopsy as the cause of an abscess in the right iliac fossa, occurred in a woman eight months pregnant. The case of Hancock,[146] no less historical as representing the first successful operation for deep-seated perityphlitic abscess, also occurred in a woman eight months pregnant. The patient miscarried four days after operation. The next case recorded is that of Porcher,[279] whose patient miscarried at five months, died suddenly and unexpectedly fourteen hours afterward, and was found on post-mortem to have purulent appendicitis and peritonitis. Hirst,[156] in 1890, operated upon a woman six months pregnant for supposed acute suppurative appendicitis. He found chronic appendicitis with a few adhesions. The patient died two days after the operation; there was no autopsy. Mixter,[234] in 1891, reports a case of appendicitis originating in the seventh month of pregnancy; successful operation was performed two months after the termination of pregnancy. Wiggin,[364] in 1892, reports an autopsy upon a woman three months pregnant, who died as the result of perforative appendicitis. Petersen,[269] in 1893, records a case of appendicitis on the seventh day following a labor at term, with rupture of the ab-

scess into the bowel and recovery without operation. Krafft[182] reports a successful operation for purulent appendicitis, performed January 29, 1893, upon a woman aged twenty-five years, four and a half months advanced in pregnancy. The patient had double pleuritis and acute endocarditis immediately preceding the appendicitis. The pregnancy proceeded to term without interruption, and terminated in the birth of a boy whom the mother, in memory of her experience, christened Malgrétout. Grandin,[157] in 1893, reports a case of acute catarrhal appendicitis six days after delivery at term; recovery without operation. Also a case of miscarriage at three months complicated with acute catarrhal appendicitis. Mundé,[250] in 1894, reports the successful evacuation of a peri-appendicular abscess in a woman eight months pregnant. A dead child was born one week after operation.

From this time onward reports of cases of appendicitis occurring in pregnant women become more numerous. Hind,[155] in 1895, reports a case having medico-legal bearings. A woman, pregnant near term, was violently assaulted. Labor set in, and death followed two days after delivery. Autopsy showed an abscess due to perforation of the appendix. Bayley,[23] in the same year, records an attack of appendicitis during the sixth month of pregnancy; recovery took place without operation, followed by delivery at term. McArthur,[218] also in 1895, reports two operations for acute appendicitis in pregnant women, both fatal. Johnson,[169] in 1896, reports a successful operation for non-suppurative appendicitis in a woman three and a half months pregnant, followed by confinement at term. Robson,[256] in the same year, records a successful operation for appendicitis thirty-six hours after accouchement at the eighth month. McCosh,[223] in 1897, reports a successful operation for appendicitis during the sixth month of pregnancy, with subsequent delivery at term. Abrahams,[2] in 1897, collected the more recent cases of appendicitis during pregnancy from the literature, giving cases of his own together with additional cases of Mundé, Harrison, Thomason, Crutcher, and Hirst. For details of these the reader is referred to the descriptions and abstracts of Abrahams. Deaver,[81] in 1898, wrote a valuable paper on appendicitis in relation to disease of the uterine adnexa and pregnancy. Finally Gerster,[131] in 1899, contributes three personal observations of appendicitis successfully operated upon during the eighth, second, and fifth months, respectively, of pregnancy, with premature labor in the first and delivery at term in the second and third cases.

**The Diagnosis of Appendicitis.**—The symptoms and signs of perityphlitic abscess, especially in the later stages of the disease, have been pretty clearly understood by the profession ever since the time of Mestivier. Beginning with 1847, the diagnosis of perforation of the appendix, or of its involvement in the inflammatory process, began to be made more frequently, among the first by Cless[61] and Hancock.[146] Gibney,[132] in 1881, wrote a very creditable paper on the differential diagnosis between appendicitis and hip-joint disease. Valuable modern contributions have been presented by Morton,[245] Deaver,[78] Meek,[230] Fowler,[122] Murphy,[251] and numerous others. Fowler[122] has gone very fully into the differential diagnosis of appendicitis in the female.

The greatest advance in the diagnosis of acute appendicitis we owe to the keen observations of McBurney,[219] which, in 1889, gave us that valuable aid in diagnosis now known the world over as "the McBurney point." Rosenthal[301] makes a weak priority claim for Traube in relation to the discovery of the point.

The elaboration and publication by Edebohls,[96] in 1894, of his method of palpation of the vermiform appendix finally made those who have become conversant with the method masters of the situation as regards the diagnosis of both acute and chronic appendicitis. It is true a thickened, inflamed appendix had previously now and then been felt through the abdominal walls. Treves,[316] in 1889, and Cameron,[53] in 1893, each reported such an experience, and Duncan,[91] in 1892, says that the position of an inflamed appendix may often be felt. The positive determination of the health or otherwise of the appendix, however, by direct examination and palpation of the organ in each and every case presenting, was considered an impossibility and never attempted previous to the publication of Edebohls.

Among those who have adopted Edebohls' method of palpation of the appendix, and who depend upon it for the diagnosis of appendicitis, may be mentioned Deaver,[78] Long,[211] Halsted,[145] Shrady,[322] Morris,[240] Noble,[256] Mynter,[254] Murphy, Beck,[27] and Kelly.[178]

**The Medical Treatment of Appendicitis.**—Volumes have been written upon the medical and surgical treatment of appendicitis. The history of the origin and development of the surgical treatment of the affection will receive attention presently. The medical treatment has received full consideration at the hands of all the older and many of the more recent clinicians, and the principles supposed to underlie it are well known to every practitioner. Few physicians advocate, with With,[367] medical treatment only for all cases. A large number of prominent internists, with Eliot,[107] Fitz,[116] and others, consider appendicitis essentially a surgical affection. As long ago as 1848, Smith[325] expressed doubt as to the efficacy of all local applications, including leeches, saying of the latter: "If you are going to use leeches in typhlitis apply them at the anus, not over the swelling." The only recommendation of electricity in the treatment of appendicitis is by Williams.[365]

**The Surgical Treatment of Appendicitis.**—The earliest recorded case of operation for appendicitis is generally credited to Mestivier,[232] who, in 1759, incised and drained an abscess in the right inguinal region. The patient died, and the autopsy disclosed an appendix perforated by a pin. A few operations for so-called perityphlitic abscess which had slowly perforated the abdominal parietes and become, in part at least, subcutaneous, were reported between 1759 and 1848. Dupuytren[93] operated thus in 1815 and 1828; Ahrt[6] in 1832, and Parker[262] in 1843. In all of these cases fluctuation was distinctly made out, and pus was encountered in the subcutaneous tissues of the abdominal wall.

Hancock,[146] on April 17, 1848, performed the first deliberate operation for deep-seated suppuration of appendicular origin. He operated on the fifteenth day of illness, and before fluctuation became apparent, reaching the pus collection by a four-inch incision extending from just above the right anterior superior spine of the ilium downward and inward along Poupart's ligament. His patient recovered. On the strength of this case Hancock proposed to operate early in these cases before fluctuation appeared, remarking that patients do not usually live to fluctuation. His teaching, however, found no echo in medical literature until reiterated by Lewis[203] in 1856. His example was first imitated after eighteen years by Parker,[262] the publication of whose case, in 1867, may fairly be said to have directly inaugurated the modern surgical treatment of abscesses of appendicular origin, and indirectly to have led to the modern surgery of the appendix.

By many writers Parker is credited with the first operation for perityphlitic abscess in 1843. Parker, in 1867, reported four cases of perityphlitic abscess operated upon, the first operation being performed in 1843. In his first three cases, however, subcutaneous fluctuation or phlegmon invited the incision, as it had

done in the cases already cited as previously reported. Parker's first operation for deep-seated suppuration, prior to fluctuation, was performed in 1866, nearly eighteen years after the original operation of Hancock. His patient also recovered.

From 1867 to 1884 the initiative taken by Hancock and Parker in opening and draining so-called perityphlitic abscesses before fluctuation was evident was enthusiastically taken up and followed, especially by American surgeons, New York being at first the chief focus of the new surgical activity. Buck, Sands, Weber, Bontecou, Burge, Whitall, Ward, Kelsey, Holden, Clarke, Ely, Raub, Bacon, Clay, North, Beach, Chamberlain, Koehler, Mynter, Weir, Byrd, Pierson, were among the earliest performers or reporters of operations for the evacuation of deeply seated abscesses of appendicular origin. Noyes,[257] in 1883, collected the reports of one hundred operations for perityphlitic abscess.

Nearly all of the perityphlitic abscesses operated upon during this period were opened by the original classical incision of Hancock. Weber[358] at first contented himself with incising down to, but not through, the fascia transversalis, and this method was even advocated as the routine procedure by Whitall.[363] Kolb,[189] in 1860, practised puncture of the abscess by the trocar and dilatation of the opening with sponge tents. Muenchmeyer,[219] in 1860, was the first to practise a counter-opening in the loin to obtain better drainage, a procedure which has since found many imitators. Buck,[43] in 1861, evacuated a pelvic abscess, presumably of appendicular origin, by puncture through the rectum. Bartholow,[19] in 1866, credits Buck with approaching a perityphlitic abscess from beneath Poupart's ligament by an incision carried through the fascia lata of the right thigh, thence working his way upward beneath Poupart's ligament to the abdomen. I have been unable to find the original account by Buck of this procedure. Barlow and Godlee,[20] in 1885, operated upon a case of appendicular abscess by two incisions, one median, exploratory in character, and one lateral, over the abscess, to evacuate the pus. This procedure has been followed in a number of cases by various operators. Kroenlein,[185] in 1887, reported the first case of operation for perityphlitic abscess under Listerism. Homans,[159] in 1886, took a decided step in advance in the case of an appendicular abscess deeply situated against the posterior abdominal wall. He opened the abdomen through the usual incision above and parallel to Poupart's ligament, and evacuated the abscess across the free peritoneal cavity while protecting the latter against infection by suitably placed packing. This has become and remained standard modern practice. Not so the procedure of Edebohls,[95] who in 1889, in a similar case, closed the peritoneum by suture, dissected it up, and opened the abscess retroperitoneally. Byrd,[52] in 1881, in a case of perforative appendicitis with two additional ulcerative perforations of the cæcum, adopted the procedure, nothing less than brilliant for that day, of converting the three openings into one large one, establishing an artificial anus by stitching the bowel opening to the wound, and irrigating and draining the free peritoneal cavity. His patient recovered. Mention should, finally, be made of Kottmann's[171] plan of opening the abscess by Vienna paste, the only advocacy or practice of this method which I have found recorded in the literature.

The above data all refer to operations for the evacuation of perityphlitic abscesses of appendicular origin undertaken before the time at which operations upon the appendix itself came into vogue. The history of the surgery of the appendix itself, and data in connection therewith, will presently receive attention. Before proceeding to this chapter of the history of appendicitis, however, two subjects, that of aspiration, exploratory or curative, of perityphlitic abscesses, and that of so-called left-sided appendicitis, deserve a moment's consideration.

**Exploratory Puncture.**—Bontecou,[41] in 1873, reported two cases of operation for perityphlitic abscess in which he employed previous aspiration to determine the presence of pus. Prior to that time we find recorded, now and then, a crude attempt to establish the presence of pus by an oblique puncture with a narrow knife, a grooved needle, or a trocar. Potter,[282] in 1879, reported a cure of perityphlitic abscess following a single aspiration of the contained pus. Peltzer,[265] in 1882, observed a cure following two aspirations of the pus, followed each time by irrigation of the abscess cavity with a solution of salicylic acid. Bull,[46] in 1886, advocates dropping all time limits and operating as soon as pus can be discovered by the needle. At about this period exploratory punctures for diagnostic purposes were much in vogue. Gradually, however, they yielded place to the increasing positiveness with which diagnosis could be reached without their aid, until at the present day probably no surgeon of any prominence either employs or recommends the needle for diagnosis.

**Left-Sided Appendicitis.**—As regards left-sided appendicitis the only genuine case thereof on record is that of Biegi,[61] which occurred in a soldier who died of appendicitis and was found on autopsy to have a complete transposition of all the viscera. The case of Bontecou,[41] in which death resulted from ulcerative perforation of the small intestine into the left iliac fossa; that of Traube,[349] of a perityphlitic abscess pointing on the left side; and the three cases reported by Fowler,[119] in which the cæcum and appendix were displaced to the left, all originated primarily in the right iliac fossa. So did the case of Coats,[69] in which empyema of the left chest followed perforation of the diaphragm by pus from an abscess of appendicular origin.

**Surgery of the Appendix.**—We have finished with the history of the era when operations for the evacuation and drainage of perityphlitic abscesses constituted, with the few exceptions mentioned, the sole surgical resource in the treatment of appendicitis, or rather of its results. We come now to the period which saw the birth of the surgery proper of the appendix itself. We will consider the surgery of the appendix as applied, first, to the treatment of acute appendicitis, and, secondly, to the treatment of chronic, relapsing, and interval cases.

The first recorded operation upon the appendix itself was planned by Dr. Mahomed and executed on August 24, 1883, by Symonds.[340] Mahomed diagnosticated a stone in the appendix. Symonds removed the stone, three-fourths by one-half inch in size, through the ordinary incision for tying the external iliac artery, approaching the appendix from behind, through peritoneal adhesions, opening the appendix, extracting the stone, and closing the opening in the appendix by Lembert sutures. The patient recovered and was cured of all his symptoms. In connection with this case Symonds becomes prophetic in relation to the future removal of the appendix in similar cases. I have found but three other instances of operation upon the appendix stopping short of its removal. Morton,[242] on April 27, 1887, removed the larger part of an appendix containing a perforation, between two ligatures, one applied near the base and one near the distal free end of the appendix. Sands,[309] on December 31, 1887, closed a perforation of the appendix by suture. Tait,[341] in 1889, slit open and drained an appendix. All three patients recovered.

**Excision of the Appendix.**—Kroenlein,[184] on February 14, 1884, performed the first removal of the ap-

pendix for acute appendicitis. He was followed in 1886 by Weir,[361] Bryant,[51] and one or two others. These earliest appendicectomies for acute appendicitis had one discouraging feature in common; they were all fatal.

The first successful removal of the appendix was performed by Hall,[143] on May 8, 1886, in an operation for the relief of a strangulated hernia. The appendix, with an abscess around it, was found among the contents of the hernial sac, tied off, and removed.

Morton,[242] on March 19, 1888, and Sands,[309] on April 17, 1888, performed the first successful appendicectomies for acute appendicitis, the correct diagnosis having been made in both cases before operation. To Morton belongs priority of performance, to Sands priority of publication. Other successful appendicectomies for acute appendicitis were performed during 1888, in the order named, by Hoffmann,[158] McBurney,[242] Cutler,[71] and Weir.[361] Hoffmann removed the appendix through a median incision, and the case of McBurney was the first in which an acutely inflamed appendix, full of pus, was removed entire and without rupture.

Thereafter removal of the appendix in acute appendicitis rapidly became a recognized and oft-undertaken procedure. As early as 1889, McBurney[219] reported seven appendicectomies of his own with six recoveries and one death, and Morton[243] four appendicectomies with two recoveries and two deaths. Since that time scores of operators number their appendicectomies for acute appendicitis by the hundreds.

Treves,[346] on June 29, 1888, performed the first appendicectomy for relapsing appendicitis. The operation as described would be classed as modern even at this day, the stump end being closed by suture instead of ligated, the abdominal wall closed for primary union, and the patient recovering. The rapidity with which operations for relapsing appendicitis, or interval operations, were adopted, and the success with which they were practised by surgeons the world over, are best evidenced by the fact that Bull,[47] as early as 1894, was able to collect four hundred and forty-four interval operations with eight deaths. It is safe to say that at the present day several thousand such cases could be collected from the literature alone.

**The Technics of Appendicectomy.**—The various surgical procedures for the simple evacuation and drainage of a peri-appendicular abscess have already been considered. It remains to record the history of the development of the technics of the operation for the removal of the appendix.

**Appendicectomy for Acute Perforative or Gangrenous Appendicitis.**—During the two or three years immediately following the first removal of the appendix for acute perforative appendicitis by Kroenlein,[181] in 1884, and the early, equally unsuccessful imitations of his example, the advocates of appendicectomy in pus cases were few indeed. The first successful cases, reported in 1888, furnished a new stimulus to surgical activity in this direction, and within two or three years thereafter the number of cases reported slowly increased. Since 1890 the large majority of surgeons with a name advocate removal of the appendix in acute appendicitis as the routine procedure, always to be attempted save under most exceptional conditions. A few surgeons claim that it is always both possible and better to remove the appendix in acute appendicitis. This advice and practice are based upon the fact that a second operation for appendicitis has become necessary in some cases in which the appendix was left at the first operation. Comparatively, however, the cases in which such a secondary operation was called for or performed are very few. Morton,[243] Patel,[263] Homans,[160] and Wolf[369] among others have put on record such secondary operations. The expedient adopted by Wyeth[374] of operating at two sittings represents an unnecessary compromise.

In direct opposition to the modern tendency to remove the appendix whenever feasible, and vainly attempting to stem the tide, we find Barton,[21] as late as 1894, and a few others even more recently, preaching the doctrine of leaving the appendix in operations for acute appendicitis, claiming better results from this practice. That this claim does not hold good in the work of the better operators goes without saying.

**The Incision in Acute Appendicitis.**—The early incisions employed in operations for acute appendicitis, when abscesses were emptied and drained only, as well as when the appendix was removed, always divided all the various anatomical layers of the abdominal wall in one and the same directions: either a little above and parallel to Poupart's ligament, or nearly vertically, just external and parallel to the outer border of the right rectus abdominis muscle. Aside from the counter-opening in the back more or less frequently practised by a number of surgeons, Dejacé[73] in one case practised lumbar incision of a perityphlitic abscess, and Gerster[130] speaks of Lange as in one instance having to abstain from removing the appendix through an anterior incision, later on removing the organ successfully through a posterior wound. Vischer,[360] in 1897, proposed a new site for the incision, placing it above and parallel to the iliac crest and running from the outer edge of the external oblique inward to the anterior superior iliac spine. The median incision has also been practised, now and then, by Hoffmann[158] and others, but has found no enthusiastic advocates.

The gridiron incision of McBurney,[220] published in 1894, represents the most modern thought and fully satisfactory technics in regards to the incision of the anterior abdominal wall practised anywhere between the outer borders of the recti and the erector spinæ muscles on either side, not only for appendicitis, either acute or chronic, but also for other intra-abdominal conditions exceptionally best approached within the limits stated. McBurney at first thought his incision unsuitable for pus cases calling for gauze packing. This judgment, however, has been reversed by the further experience of a number of American operators, among them the writer, who constantly use this incision in cases of acute appendicitis, and consider all the other incisions already mentioned as antiquated and out of place in up-to-date surgery. The slight modification of the gridiron incision proposed by Elliot,[105] who cuts the fascia of the external oblique horizontally, while attempting to refine on the principle enunciated by McBurney, is of no practical importance.

**The Incision in Chronic Appendicitis.**—The comments made anent the first incisions practised for acute appendicitis hold good also for those made for the removal of the appendix in interval cases, with this important exception: that, beginning with the very first removal of the appendix for recurrent inflammation by Treves, the abdominal wound has been very generally closed for primary union without attempts at drainage. The gridiron incision, originally devised and brought forward by McBurney for cases of appendicitis not requiring drainage, but equally applicable to pus cases, represents the first giant stride forward in the surgery of the incision made for the removal of the appendix in chronic appendicitis. Battle,[23] in 1895, gave us the incision through the right rectus abdominis muscle, which in chronic appendicitis has become the successful rival of the gridiron incision of McBurney. The rectus incision of Battle may be found admirably pictured and described as the simple incision by Deaver[79] in 1896. Curiously enough, in 1897, Jalaguier,[166] Kammerer,[127] and Lennander[195] published the Battle incision, each apparently under the

impression that the incision was original with himself. The lumbar incision for chronic appendicitis was brought forward by Edebohls,[100] in 1898, as applicable to cases in which right nephropexy and appendicectomy were called for in the same patient.

About ten centimetres seems to be the length of incision usually accepted as required in acute appendicitis. In the surgery of chronic appendicitis Morris,[230] in 1893, first recognized that such long incisions were unnecessary, and loudly called for the one-and-a-half-inch incision. He has since been outdone in this direction by Scott,[311] who writes on "the incision less than one and a half inches long in appendicitis." The writer[103] has recently recorded his views on the subject, and will close with the statement that the only incisions necessary and permissible in the modern surgery of the appendix are the gridiron incision of McBurney, the rectus incision of Battle, and, perhaps, the lumbar incision of Edebohls.

**Technics of the Stump.**—The treatment of the stump left after amputation of the appendix has occupied a great deal of the attention of surgeons. In some cases of acute appendicitis, with gangrenous destruction and disintegration of the entire appendix and even of greater or less areas of the cæcal walls, the question of a stump and its treatment does not arise. In such cases the damage must be repaired by suture, and the danger must be minimized by the usual gauze packing and drainage, or by suture of the damaged bowel to the abdominal wall as practised by Byrd,[32] Bunner,[19] and others. Simple ligation of the stump, though still very generally practised, cannot be considered a perfectly safe procedure. Dock[79] has put on record a death from simple ligation, and the writer knows of another unpublished case in which intestinal leakage and fatal peritonitis followed the slipping of a ligature placed around an appendix stump.

The example of Lautard,[174] who amputated the tip of the appendix and sewed the long stump to the abdominal walls, has found no imitators.

Invagination of the ligated stump has been attempted by Smith[58] and many others since his time. All such attempts are illogical and have necessarily met with failure, as complete invagination of a ligated stump is an impossibility. The most that can be accomplished is to depress a ligated stump and cover it over with peritoneum, a procedure which Stimson[287] was the first to condemn as "bottling up" of the appendix.

Closure of the open ends of the appendix by suture was practised by Treves[346] in the very first case of removal of the appendix for recurrent appendicitis, the mucous and muscular coats being united by suture. Treves, however, found it impossible in his case to sew the peritoneum over the free end of the stump, which procedure appears to have been first accomplished by Allingham. Monks,[236] in 1890, improved this step of the technique by first inverting the cut end of the appendix and then closing the inverted edge by suture. Ruth,[306] in 1895, sutured the cut edges of the appendix stump, inverted the stump, and approximated the peritoneum by suture.

Inversion of the appendix stump without previous ligation and suture was practised by Dawbarn[76] as far back as 1890 or 1891. The correct principle underlying Dawbarn's method was clumsily imitated by Plummer,[276] who slits the appendix stump upward at two opposite points, trims and inverts the flaps, and sutures the serosa—and by Bloch,[18] who uses a temporary suture through the lips of the appendix stump, passes the threaded suture through the cæcal wall opposite the appendix, from within outward, withdraws the suture, and closes the peritoneum over the inverted stump.

Price[284] and Eastman[84] do away entirely with a stump by excision of the entire appendix and suture of the resultant hole in the bowel wall. Edebohls[99] originated inversion of the entire, uncut appendix, the only procedure which does away with the necessity of opening the bowel and with the resultant risk of infection. His procedure, so far as I am aware, has found but one imitator, Fowler,[121] whose first and only case of inversion of the entire appendix for chronic appendicitis ended fatally as the result of the operation. Against this, however, stand considerably more than one hundred cases of inversion of the entire, uncut appendix for chronic appendicitis, at my own hands, without a single death.

**Septic Peritonitis; Drainage; Accidents.**—The treatment of the diffuse septic peritonitis accompanying appendicitis has received attention at several hands. McBurney,[221] in 1895, wrote the most important clinical contribution to this aspect of appendicitis, advocating free flushing of the peritoneum with drainage, procedures practised by Byrd[32] as early as 1881. Pond[278] added to these resources, in extremely bad cases, incision of the intestine and suture of the incision lips to the abdominal wound, permitting of the direct introduction of salines, stimulants, etc., into the intestine.

Gauze drainage is all but universally used in pus cases, either alone or combined with rubber or glass drainage tubes. Morris[240] first employed an iodoform wick, and later a special device consisting of a slender piece of gauze wrapped about with perforated rubber tissue. As regards the use of iodoform gauze, opinions of experienced men vary widely. Morris, for instance, in 1897, published a tirade against the use of gauze, iodoform and plain, while Murphy, in the same year, returns to the use of iodoform gauze after having completely discarded it for a time.

Very recently a tendency to close immediately the abdominal wall for primary union in some cases of appendicitis with pus is becoming manifest. Schueller,[313] in 1889, was the first, I believe, successfully to close the abdomen at once and entirely after an appendicectomy at which he found turbid serum in the peritoneal cavity. Clark,[55] in 1897, alludes to instances of similar practice, and Boldt informs me that he has several times operated successfully in the same manner in cases in which a small amount of pus was present.

A curious accident, tearing off of the distal end of the appendix during enucleation of the latter, and failure to find again the distal end, is recorded by Huntington.[163] The writer has had a similar experience; both cases ended in recovery, without drainage. Hutchinson[162] reports an operative case in which he found the appendix at some distance from the cæcum, from which it had entirely separated by sloughing.

**Statistical.**—Autopsy statistics of appendicitis, large and important for the time at which they were presented, have been given by Leudet,[201] Finnell,[115] Toft,[311] Fitz,[116] Einhorn,[105] Wallis,[356] Ribbert,[287] and Robinson.[295] Kleinwaechter[197] and With[367] have furnished statistics regarding the duration of appendicitis under medical treatment, while Sands[308] and Fitz[117] investigated the mortality under medical and under surgical treatment. McBurney[221] presents personal statistics of operations for appendicitis in the presence of diffuse septic peritonitis. Von Mayer[354] gives us a very unique, practical, and interesting study of seventy-five operative cases of chronic appendicitis. Of these, thirty-three presented clinical symptoms corresponding to the lesions found, thirty-two presented no clinical symptoms, and ten had severe symptoms with no lesions. Statistics of operative cases, with mortality, have been published by Clay,[59] Bull,[47] MacDonald,[213] Murphy,[252] Johnson,[169] Kuemmell,[188] Sonnenburg,[330] Deaver,[80] Halliday,[141] and very numerous others.

**Illustrations.**—Appendicitis has furnished a favorite subject for the artist's pencil and brush, and it is not too much to say that perhaps upon no other subject in the entire range of pathology has such widespread, profuse, elaborate, and beautiful illustration been lavished. I call attention in the following to those illustrations which have struck me as particularly noteworthy; they constitute, however, only a modicum of the whole.

The anatomy of the appendix and its vicinity has been thoroughly illustrated by Little,[208] Schueller,[313] Lockwood and Rolleston,[209] Levings,[202] Kelynack,[177] and Jonnesco.[168] The general pathology has been well pictured by Fenger,[112] Fowler,[121] Jessop,[167] Plummer,[276] Lannelongue,[193] Smith,[326] and Sonnenburg[325] among others, while the histo-pathology has been especially well delineated by Letulle and Weinberg.[200] Chronic appendicitis has received the artistic attentions of Foges[118]; interval appendicitis those of Abbe[1]; appendicitis obliterans those of Senn[316] and Zuckerkandl[376]; and the location of abscesses those of Harris.[147] Intestinal strangulation following appendicitis has been pictured by most of those already enumerated as having described cases, while some of the operative sequelæ have been delineated by Peck.[261] Cysts and cystic degeneration of the appendix have been well pictured by Gruber,[139] Gouillioud,[136] Shoemaker,[321] Sonnenburg,[327] and Coats.[63]

Among illustrations of other pathological conditions affecting the appendix the following may be mentioned: Invagination of the appendix, by McKidd[225]; prolapse of mucous membrane of the appendix, by Rolleston[300]; thrombosis of appendicular vessels, by Dieulafoy[87]; tuberculosis of the appendix, by Apert[10]; and primary cancer of the appendix, by Mosse and Daunic.[247] The technics of the operation for appendicitis have been abundantly illustrated by many writers, among others by Ruth,[306] Deaver,[79] Fowler,[124] and Morris.[240] The article of Ruth contains beautiful illustrations detailing the technics of the stump. Deaver's admirable plates are the only ones I have found illustrating the rectus incision. Five cuts detailing post-operative sequelæ in a very interesting case are given by Peck.[261]

**Literature.**—The entire literature of appendicitis, complete to the beginning of the year 1899, and including, in addition, about fifty numbers appearing during the present year, has been consulted in the preparation of this article. This vast literature embraces, as already stated, more than twenty-five hundred journal articles, dissertations, and books. A complete bibliography, prepared by the author, may be found in the library of the New York Academy of Medicine, where it is at the disposal of any one who may wish to consult it.

The appended bibliography of three hundred and seventy-six references is believed to include nearly all of real value that has been published upon the subject of appendicitis. It includes papers and books important and valuable for the time at which they were published, together with a number of articles to which reference became necessary in the preparation of this historical review.

## MORPHINISM AMONG PHYSICIANS.[1]

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.

In 1890 I was appointed chairman of a committee to collect and study statistics of the prevalence of alcohol and opium inebriety. During this interval of nine years a large number of statistical observations and data have been gathered. From these facts I present a preliminary report confined exclusively to the study of morphinism among physicians. I shall give conclusions rather than tables, and general facts rather than exhaustive studies. These data came almost exclusively from physicians who were requested to ascertain the number of medical men of their acquaintance and vicinity who used alcohol and opium, also to give a percentage of the whole number.

In this way a history of thirty-two hundred and forty-four physicians residing in the Eastern, Middle, and some of the cities of the Western States was obtained, of whom twenty-one per cent. were found using spirits or opium to excess. Six per cent. of this number used morphine or opium persistently. Ten per cent. were using opium or other drugs secretly outside of this number. Over twenty per cent., including this number, used spirits in so-called moderation. In another study of one hundred and seventy physicians, seven per cent. used opium or morphine, and six per cent. were secret drug takers. From the personal observation of a number of city physicians who have a large acquaintance with medical men, from eight to ten per cent. were found to be either secret or open drug and morphine habitués.

These figures appear to be approximately correct, and show that from six to ten per cent. in this country are opium inebriates. This is considered a conservative statement, considering the fact that drug takers, and physicians in particular, are secretive and conceal their use of drugs, especially when it implies weakness and reflects on their social standing.

There are many reasons for the support of the statement of Dr. Elain that a large percentage of physicians suffer and die from drug treatment of themselves. They begin to use spirits, opium, and other drugs for functional and transient disturbances, and later contract serious organic disease, the early drug-taking having been a contributing cause. A physician who in middle life is excessively neurotic and neurasthenic, or who is rheumatic, has organic heart disease or neuritis, or chronic gastritis, is often suffering from the results of excessive spirit or drug taking in early life. The early user of morphine, chloral, cocaine, and other drugs of this class, who after a time stops all use of them, suffers later from varied and complex neuroses. In the same way the spirit drinker finds in later life serious organic diseases springing up without any apparent cause. In reality they are traceable to the poisonous effects of drug taking early in life, although a period of abstinence may have intervened. Such cases are not uncommon, and occur in persons by whom this drug taking is concealed to a large extent. There is no doubt a great deal of invalidism, diseases, and failures among medical men that are due directly or indirectly to secret drug taking. Morphinism among physicians is usually associated with the use of the drug by the needle. Opium in the tincture and gum is also used, but less prominently. The effects are the same, only varying in intensity and rapidity. The opium users are often alcoholic inebriates switched on to a parallel road. After a period of so-called moderate or excessive use of beer, wine, or strong spirits, either secretly or openly, they turn to the tincture or powdered opium. From this time their career is one of progressive organic degeneration. The tendency is toward imbecility, and, although they may be active for years, a low form of invalidism follows, and acute, fatal inflammations are always impending.

The physician who uses opium is always somnolent, serene, and meditative in manner. Except an increasingly defective memory and degenerating ethical sense, and irregularities of conduct, with a certain lividity of face, there is little to indicate his condition.

On the other hand, the morphinomaniac shows great extremes of emotion. At times he will be talkative, and sensitive to his surroundings; then silent, indifferent, irritable, or violent in his impulses and talk. He will at times be very brilliant, make a clear diagnosis, perform a difficult operation, and even deliver a lecture with spirit and energy. The same impaired memory and ethical sense appear, although more concealed.

Morphinomania tends toward acute mania and suicide, with the same impending acute inflammations. A certain number of morphinists have been wine, beer, and spirit drinkers, and while suffering from the effects of excesses have found quick relief from morphine. Later they have in part or altogether given up spirit and used morphine. Periodical drinkers not infrequently find the same relief from morphine and use it to break up the drink storm or lessen its effects. They begin at intervals to use morphine and continue it steadily. Another class suffer from some neuralgic affection or spasmodic pain, for which morphine gives instant relief, and use it afterward as a specific remedy. A class quite as numerous find in morphine a supposed stimulant when exhausted, but in reality a narcotic which covers up the protests of nature. They continue its use until it is difficult to stop. Insomnia, strains, and drains, and all the complex symptoms of exhaustion and poisoning, find most fascinating relief in using morphine by the needle.

Morphinism is clearly built up from a foundation of neurasthenia, anæmia, hyperæmia, and from hereditary nerve defects; also from drug taking and intoxicants, nutrient derangements, and the complex injuries to the nerve centres. To this are added the various disturbances which come from irregularities of life and living and from the nerve shocks of failures, successes, and emotional strains. Following these states are both physical and psychical pains, brain and nerve perturbations, muscular and organic weariness, with depressions. For these the needle is a panacea.

There is a painful fascination in the rapid, complete change and transition which follow the needle. To the psychopath, inherited or acquired, this is a revelation, and no other form of administering morphine can be compared with it. This actually develops a needle

[1] Read at the meeting of the New York State Medical Association, October 25, 1899.

mania, and nearly all morphinists are hypodermatic maniacs. The withdrawal of the morphine is unnoticed as long as the needle is used. In a certain case, a physician used the needle with water, supposing it to be morphine, for two years after the withdrawal of the drug, under the direction of his partner.

It is the common experience to keep up the use of the needle for its mental effect long after the morphine is abandoned. Even then it is difficult to break up the mania for this form of drug using. It has been stated, with some basis of fact, that the constant administration of drugs by the needle, and particularly morphine, is a prominent symptom of a morphinomaniac physician. The observation is often made that some of the most enthusiastic defenders of the use of morphine by the needle were confirmed users of the drug. Two therapeutists and authors who praised this form of medication died from the excessive use of the drug. Thus the needle delusionist is often his own doctor and patient. This is true of other drugs, in which the physician's personal experience is reflected in his enthusiastic use of the same drug upon his patients.

The medical morphinist may succeed in concealing his use of morphine for a variable time, but its effects on his thoughts and conduct cannot be long covered. He will early begin to show carelessness in conduct, neglect of duty, loss of personal respect, and emotional changes. Along with this appear a childish egotism and a disposition to criticise and to expose the weaknesses of others. A recent incident of this nature was the sudden slanderous disposition manifested by a quiet physician, who was previously reticent as to the faults of others. For two years he created a good deal of bad feeling by his foolish criticisms and falsehoods. He was arrested for slander, and his morphinism was discovered. The egotism grows, and becomes a veritable delusion that his condition is concealed and unknown to others.

In some cases intense aversion exists to acknowledging the fact of using morphine, and keen pleasure in concealing and denying its use. This low regard for the truth is an ethical defect common to nearly all cases of morphinism. It usually is childish and apparent, but often extremely subtle and cunning. In most cases it applies to all the relations of life; in others it is partial, and confined to the morphine addiction. It shows the damage to the sensory and reasoning centres as well as the effect on the higher psychical brain. The defect also grows, and the danger of his condition is minimized, while his ability to stop and to treat himself increases in his own opinion. Credulity alternated with distrust follow each other, and at one time a good physician will accept and use secret drugs, and do many unreasoning things. Later, he will doubt everything, and be suspicious of every condition of his surroundings and his relations to them. This erratic conduct will be seen in his indorsement of new and strange theories. His former politics and religious views will change, and he will show distrust, and deceive his nearest friends. He will make strange acquaintances, write eccentric papers for the journals, or read them to the local society. A study of papers in medical journals will show the writing of concealed morphinomaniacs and cocaine takers. The one will be startling, inconsistent, and assertive; the other will be a continuous, monotonous flow of words, pointing in every direction, and never ending. A voluminous medical writer under my care for morphinism has never written a line since his recovery. Before, he wrote from one to two papers a week, and read them before all the societies in his neighborhood. Often morphine and opium are the subjects of their writings, and while they may read voluminously on this subject, they write strangely and erratically. The proportions are distorted. Insignificant parts of the subject are exaggerated, and central truths minimized.

Morphinists are also prominent as writers on several topics in medicine, and report extraordinary gynæcological cases and many startling conclusions. In their personal intercourse they are boastful, and have marvellous experiences, and lead all others in business and mental activity. With these mental changes there is increasing abruptness and coarseness of manners and language, and neglect of personal appearance. The untruthfulness merges into deceit and dishonesty and often senseless stealing. There is increasing suspicion and distrust. Physically, there is general anæmia, with digestive disturbances, and neuralgias, both general and local, are prominent.

After a time the medical morphinist will accede to the pressure of friends and try to stop its use. He may succeed, but soon relapses. Then he will try again with the same results. Or he will turn to spirits or other drugs, and after a time give them up, only to return to morphine. All sorts of plans and specific remedies are tried, but all fail. The gradual reduction, extending over months, ends in disgust and a return to large doses. All this experience increases his egotism and confidence in his ability to escape by his own powers, if he can only have his own way and control the conditions. Finally, after trying various means and measures, he consents to go to an institution for legitimate treatment. He is either skeptical and suspicious, and secretes morphine in his clothes for emergencies; or he is credulous, and has exaggerated notions that the morphine can be taken away without the slightest discomfort, or even without his knowledge or without his feeling it.

Such have a fixed conviction of mental strength equal or superior to others regarding the use of morphine, particularly from experience enabling them to decide on the measures and means for successful treatment. Like many alcoholists, they assume superior knowledge of their own case and how they should be treated, and constantly review their own symptoms and reason out the means for successful treatment. As the symptoms change, the diagnosis and treatment should change; the result is that they soon become disappointed or dissatisfied, and secrete morphine for possible emergencies of the future, or go away condemning the asylum and its management for their failures. In this way the deceptive egotism and secretiveness, with delusional reasoning, make the medical morphinist a most difficult patient to treat.

The removal of the morphine and the restoration of the functional derangements are practically simple with the full control of the patient and his surroundings. The treatment and after-care require far more skill and tax on our therapeutic resources. The abandonment of the needle at the start, and the change to some other form of opium or other narcotic to lessen the acuteness of the withdrawal symptoms, then the slow or rapid withdrawal of the drug, are the most practical means. The hot-air bath with massage daily, and more frequently if necessary, is the most valuable. Strychnine, acids, and some of the bitter tonics are useful. The bromides of sodium, cannabis indica, hyoscyamine, and the milder sedatives, such as valerian and lupulin, may all be used to relieve the acuteness of the withdrawal symptoms.

The mental effect of remedies and efforts are often more effective than in any other disturbance, and constitute a very important means of treatment. The power of suggestion, and faith in certain drugs, will overcome the most distressing symptoms. An unknown drug has often broken up the insomnia and the reflex disturbances. One of the specific opium drugs, which has brought great wealth to the proprietor, contains only lupulin and acid, but is given with great

minuteness of direction, and sustained by a large book of most extravagant certificates of former cures.

A boisterous, emphatic clergyman impressed a morphinist doctor that he would be lost if he did not give up morphine at once. He went to bed, and from the dominance of this idea overcame all the common symptoms, and made a good recovery. A physician under my care, on the eve of marriage, gave up at once the use of ten grains of morphine daily, and had none of the common after-symptoms from some mind effect. The hypersensitiveness, both mental and physical, requires mental means in the treatment as well as exact surroundings and exact care.

The medical morphinist is dangerous to himself and to others, and should place himself under treatment at once. It is folly to attempt to do this at home and under his own care. He may succeed in withdrawing the drug; but relapse will be certain, and the failure will leave him worse than before. He should go under the care of some one in whom he has confidence, where special surroundings and special means can be used, and where the work of recovery can be made exclusive. Then he should give up all ideas of self-treatment, and trust to others without question or doubt. The morphine can be removed in a few days, and then the real treatment will begin; and this can be carried on in lines familiar to the patient, and with his full co-operation. The morphinist will discover the damage done to his system only when the drug is removed, and with a good adviser may do much permanently to repair it and be a healthy man in the future. As in other cases, permanent restoration depends upon an early recognition of his trouble, and the prompt use of exact means under the control of the best men, in the best surroundings, carried on for a sufficient length of time to insure permanent results. Particularly the causes for the using of the morphine must be removed.

I cannot stop without calling attention to the fact that morphinism is increasing among physicians. The reports from private asylums and public hospitals show that within five years medical men form a considerable part of their inmates. Specialists of nervous diseases sustain the same fact. The young and the middle-aged men are the most common victims. Often they are from that class of delusional therapeutists who want to prove everything by personal experience, or who have exalted conceptions of the power of drugs, and believe that researches in that direction will open the road to a physical millennium.

Perhaps morphinism among physicians is rather a sign of the stress and nervous strain in the world incident to civilization, or common to the overcrowding and overwork demanded of the successful man. At all events it is one of the most fascinating and serious modern diseases which can come to the professional man. Teachers of therapeutics by their graphic descriptions have roused a morbid curiosity which has been fatal to the student in after-life. I have collected a number of instances of this kind, showing that the danger of making morphinists in this way is not only possible but is a reality to an unknown extent.

I conclude with a caution which cannot be stated in words too strongly: Never use morphine by the needle on yourself, and never use it except by the counsel of a trusted medical adviser. Never give morphine to a neurotic or psychopathic physician until you are satisfied that it is the best remedy that can be used. If you are using morphine, abandon it at once, or make every effort to do so at the earliest moment.

## AN EPIDEMIC OF INTERCOSTAL NEURALGIA (?).[1]

By THOMAS F. REILLY, M.D.,

NEW YORK.

SPORADIC cases of intercostal neuralgia with an accompanying herpes zoster are of tolerably frequent occurrence, and attract little attention. It was the good fortune of the writer to observe during the early part of the past summer a series of cases of a disease that was similar, in some respects, to the classical zoster and neuralgia, but differing from it in several important features. About the middle of June cases began to present themselves with the following history. After a few hours of malaise and chilliness, a sense of uneasiness, and later of pain, manifested itself in the side, usually over the left hypochondriac region. This increased in severity, and within half an hour became almost unbearable. The pain was continuous, with frequent exacerbations. The sensation, as felt by myself (having been one of the early sufferers), was such as one would expect if the spleen was swelling rapidly, and pushing out the ribs, producing the pain characteristic of distention. The pulse was 100, respirations 24, and temperature 101° F. Every movement intensified the pain; deep inspiration or coughing rendered it excruciating. After two or three hours a profuse sweat appeared, and the pain began to diminish. Three or four hours later the pain had entirely vanished. However, the general sense of uneasiness, coated tongue, and gastric disturbances continued, while the temperature dropped to 99.5° F. The next afternoon, or that of the following day, the paroxysm was repeated. On the second or third day a herpetic eruption usually appeared. Four paroxysms were the largest number that I observed in any case. For a period of a week or more following the last paroxysm there was a sense of uneasiness with an occasional pain in the affected region. This was usually more marked in the morning. From the beginning to the end of the disease perspiration was very profuse and more or less constant. It had about the same odor in all the cases. The prostration was very marked throughout the whole course of the disease. Most of the cases were not so severe as the foregoing, and toward the end of the series usually but a single paroxysm occurred.

I observed fourteen such cases within a period of five weeks. Several of my friends each treated a similar number. All of the cases occurred in the upper part of the city on the west side.

It has been customary to regard herpes zoster as a necessary accompaniment of this form of neuralgic pain, and the affection is usually described as zona or herpes zoster. In four of my cases a herpetic eruption did appear along the course of the intercostal nerves in the painful region. In eight cases the herpes appeared on the face or mucous membranes, and some of the severest cases were in this group. In two mild cases I did not observe the herpetic eruption. This is opposed to the view formerly held, that the herpetic eruption must needs appear over the nerve tract of the painful region. In more than half of the cases a pharyngitis appeared on the seventh day. Pruritus of the entire body occurred in five cases. In three cases a small papular eruption, general in distribution, made its appearance toward the end of the second week. In three cases the pain extended over the region of the seventh, eighth, and ninth intercostal nerves on the right side, extending from the mid-axillary line forward. In three other cases it attacked both sides alternately during the same paroxysm. Obstinate constipation was a marked feature in all of the cases.

[1] Read before the New York State Medical Association, October 26, 1899.

Vomiting was a prominent feature in four cases. All of the patients were in good health previous to the attack. As far as I could ascertain there were no sequelæ.

Epidemics, similar in many respects to the foregoing, have been reported by Kaposi, Wetz, and others, but a zoster always accompanied the cases reported. There is a wide divergence of opinion as to the nature of the disease. Much of this confusion in the past was due to the confounding of ordinary, simple neuralgia with this disease. That it is not a neuralgia, in the ordinary sense, is evident for the following reasons: In all cases of neuralgia examined at the Massachusetts General Hospital by Cabot, leucocytosis was not found in a single instance. All of the cases examined in this series showed leucocytosis. In the second place, the presence of continued fever, gastro-intestinal disturbances, sweating, and prostration are evidences of a general toxæmia. Again, in true intercostal neuralgia the so-called Valleix points of tenderness where the nerve becomes superficial can be demonstrated. In no case could I elicit this sign, although always examined for.

The trend of recent opinion is to regard it as a constitutional disorder, due to an acute infection. Paul Gerne has pointed out that it corresponds in every particular to the acute exanthemata; that one attack generally confers immunity, and that the disease often occurs in epidemics lends color to this view. In passing, it may be mentioned that three of my cases occurred in one house, and two in another. Hay has called attention to the general glandular enlargement in these cases. As a result of microscopical examination of a gland from such a case, he has discovered a bacillus which he thinks may possibly be the cause of the disease. Kaposi states that epidemics occur in Vienna in the spring and autumn, and thinks the outbreaks are influenced by atmospheric conditions. Wishing to ascertain if there was any connection between the atmospheric conditions and the present epidemic, I wrote to Local Forecaster Emery, of the United States Weather Bureau, for the requisite data, which he very kindly placed at my disposal. From a study of this material I find that the mean temperature for the period from the middle of June to the middle of July was slightly higher than was usual. The number of cloudy days during the two months was 41; the average humidity, 70: mean atmospheric pressure, 30. There were no great sudden variations in either temperature or pressure. The prevailing winds were south and northwest. The velocity of the wind was a trifle higher than usual. Finally, to use the words of the forecaster, this period does not show any unusual meteorological conditions.

Winfield found the plasmodium malariæ in seventy-five per cent. of his cases, and thinks that this is the usual cause of the disease. The paroxysmal nature of the affection is a point in favor of this view. In the blood of a few patients examined, I failed to find the plasmodia, but, on the other hand, noticed a marked leucocytosis. Quinine seemed to have no effect and a previous malarial history was rarely obtainable. In none of my cases could the spleen be palpated. The immunity from further attacks, that is said to follow this disease, is strong evidence against the malarial theory.

Since writing the above my attention was called to two articles in the *Münchner medicinische Wochenschrift* for August and September, describing an epidemic of neuralgia in a small German city. Over one hundred cases are reported in detail. Various parts of the body were involved. The presence of herpes was variable, and did not seem to bear any relation to the nerves affected. The observers did not notice any rise of temperature accompanying the disease. More females than males were affected, and genital disturbances were present in many cases. The epidemic was restricted mostly to one quarter of the city, and the observers think it was due to an acute infectious agent.

**Treatment.**—After the useless employment of quinine in massive doses, I had recourse to salol and phenacetin, with an occasional dose of chlorodyne or morphine. Strapping the side with rubber plaster gave relief at once, and when the zoster was not present did more to shorten the disease than all other measures. A mustard plaster applied over the affected region during the paroxysm was also of some service in relieving the pain.

## HYPERTROPHIES IN THE TONSILLAR RING.*

By DANIEL B. HARDENBERGH, M.D.,

MIDDLETOWN, N. Y.

This subject is presented from the standpoint of the general practitioner whose work, whether in city or rural district, lies outside the great centres; who has not the specialist readily accessible; and upon whose knowledge and skill the larger portion of his clientèle is immediately dependent. At a recent meeting of the British Medical Association the president in his address placed the consideration of these growths in equal prominence with the great medical topics of the day. The general interest of the topic alone is pleaded in apology for this paper.

At either side of the pharynx, between the anterior and posterior pillars, are the faucial tonsils; at the centre of the roof of the naso-pharynx, the pharyngeal or Luschka's tonsil: at the base of the tongue, the lingual tonsil. These are structures of the same histological character—a collection of lymph follicles or adenoid tissue held together in a loose fibrous network of connective tissue. In the faucial tonsils the lymph follicles are arranged in groups which occasionally sink below the general surface of the mass, thus forming crypts. Such tissue usually marks the opening of canals either embryonic or permanent, upon the mucous-membrane surface. The faucial tonsils mark the openings of the gill-slit orifices of the embryo; the third tonsil, that of a duct which in the embryo traverses the floor of the pituitary fossa and opens upon the roof of the pharynx. The so-called tonsillar ring, or ring of Waldeyer, is completed by small cushions of lymphoid tissue about the orifices of the Eustachian tubes. Kirkes and Flint state that the function of these struc-

* Read at the semi-annual meeting of the Orange County Medical Society, October 10, 1899.

tures is the production of a lubricant to aid in deglutition. Other physiologists say that all lymphatic tissue, whether in the form of a simple collection of lymphatic cells scattered through the nose, Eustachian tubes, or pharynx, or collected into prominent groups as in the naso-pharynx, fauces, or at the base of the tongue, are germinating centres for leucocytes. Again, the position has been taken that these masses of lymphoid tissue are abnormal and of pathological import alone. Flagg[1] classes them "among the dangerous rudiments in man." It is argued that the tonsils were of use in a gill-breathing period of evolution; but now the embryo, while in its development ridding itself of the gill slits, has not disposed of the structures marking their termini. The tendency toward the disappearance of the pharyngeal tonsil in the first few years of life, and of the faucial tonsils at puberty, as well as the fact of their larger relative size in the embryo, strengthen the contention of their rudimentary and obsolete nature.

In hypertrophy there is an increase in all the tissues that constitute the structure. The follicles occasionally become over-distended with secretion, giving rise to a fetid discharge. The enlargement of the third tonsil has been termed adenoid vegetations. The frequency of its occurrence and its clinical importance were first brought to the attention of the profession by Meyer, of Copenhagen, in 1868. It is essentially a disease of childhood, though not confined to that period. Hypertrophies of the faucial tonsils have a greater tendency to continue into adult life, and Bosworth distinguishes in this situation a hyperplastic following the hypertrophic form, and in which the new connective tissue takes the place of the lymphoid. In these cases the glands become hard and fibrous in character.

There is an hereditary element in the causation. The affection tends to occur in several members of the same family. The most frequent cause is repeated and neglected attacks of catarrhal inflammation of the nose and throat. The infectious diseases of childhood are also causes. The obstruction from acute rhinitis by rarefying the air in the naso-pharynx causes distention of the post-nasal lymphoid tissue, and the hyperæmia thus produced aggravates the condition.

Hypertrophy of the lingual tonsil is comparatively infrequently encountered, and is essentially a disease of adult life. Enlarged faucial and pharyngeal tonsils obstruct nasal respiration, and thus produce mouth-breathing. This may be constant or limited to the period of sleep. During sleep the mouth becomes dry; snoring is induced; and the subject, usually a child, is restless. At times somnambulism results. Nocturnal enuresis occurs in some cases. The obstruction to respiration may be great enough to produce dyspnœa. The child is unable to run about without distress, remains relaxed, and sweats easily. Cough is a common symptom, and is often paroxysmal. There may be difficulty in swallowing. The voice may be muffled and suggestive of encroachment upon the naso-pharyngeal space.

Inability of mental application, accompanied by an expression of stupidity in the facies, as a result of enlargement of the pharyngeal tonsil, is well known to occur. Irregularities in the development of the palate, alveolar arch, and teeth have been shown to result.

In assigning to hypertrophy of the tonsils, more especially of the third, the primary cause of the most common ear diseases, there is unanimity of opinion. Miller[2] says that acute otitis media "comes most frequently by extension from the naso-pharynx. Hypertrophied tonsils undoubtedly have a similar effect upon the ear, but adenoid growths, which so often coexist with them, are no doubt more frequently responsible."

Dench[2] affirms of chronic catarrh of the middle ear: "My own belief is that certain conditions of the nose and naso-pharynx, such as enlargement of the faucial tonsils, etc., are hereditary. Any of these conditions predispose to inflammation of the middle ear"; also that "of local causes the most important is probably enlargement of the pharyngeal tonsil."

Buck[2] assigns as the three factors in perpetuating chronic suppuration of the middle ear: "First, lowered vitality; second, intra-tympanic stagnation of the discharge; third, the presence of a mass of hypertrophied lymphoid tisssue in the vault of the pharnyx"; and states that "the discharge in the cases where the main cause is to be found in hypertrophied tissue in the vault of the pharynx consists largely of ropy mucus. The discharge is apt to be intermittent, sometimes stopping altogether during the summer months, and is entirely free from any unpleasant odor."

As hypertrophy in the tonsillar ring, especially in the vault, is the most important local cause of inflammation of the middle ear, it follows that such hypertrophy is more remotely the chief local factor in producing deafness.

The frequency with which subjects of enlarged tonsils suffer from recurrent attacks of acute tonsillitis is a matter of general observation. Newcomb[2] says: "Chronic enlargement of the tonsils naturally invites recurring inflammation." F. Jessen,[3] senior physician to the Vereins-Hospital of Hamburg, sums up the literature and reports a number of cases showing that the tonsils are places of entrance of infection in many instances attributed to different origin, some of them even without any manifestation of disease upon the surface of the tonsils. He likewise contends that many and varied cases of so-called scrofula are generally infections from some portion of the lymphoid ring and often promptly cured by removal of the diseased tissue.

The lower segment of the ring is easily viewed, the faucial tonsils are seen with moderate, the lingual with forced, depression of the tongue. The pharyngeal tonsil is difficult of examination. Excepting in very skilled hands the use of the post-nasal mirror is usually unsatisfactory and often impossible. The same may be said of the examination with the finger tip without anæsthesia. Moreover such an examination renders subsequent measures more difficult. Farlow[2] remarks that "the child has usually had all the examination it will submit to when the finger has once been behind the palate." Frequency of association of hypertrophy of the lateral tonsils with that of the superior will be the most constant guide to diagnosis of the latter.

Dench[2] states "that an enlargement of the faucial tonsils is almost invariably accompanied by a similar condition of the pharyngeal tonsil"; Dawbarn,[4] that "nine out of ten pharyngeal tonsils are also cases of large faucial tonsils." The ground was taken by Rice at the recent meeting of the New York State Medical Society, that when from examination of the faucial tonsils, and the presence of symptoms, hypertrophy of the pharyngeal tonsil can be inferred, the diagnosis is best made with the curette. Operative relief may be secured in appropriate cases, and in the few instances in which diagnosis is not established no injury will be done.

The treatment of these hypertrophies is removal. Cousins,[5] in referring to pharyngeal vegetations, asserts "that the number of young persons who have been saved from life-long deafness by the removal of these obstructing glands amounts already to hundreds of thousands, and that hundreds of thousands more will be delivered from this terrible affliction in future times." Senziak[6] sums up the advantages of removal of these same growths as follows: Re-establishment of nasal respiration; improvement of the general health;

favorable influence on the intellectual faculties (relief of nasal aprosexia); improvement of hearing and removal of certain diseases of the ear; favorable effect on deaf-mutism; disappearance of local disease of the nose and pharynx; relief of certain reflex neuroses such as asthma, cough, enuresis, etc.; cessation of local hemorrhages, and improvement of defects in speech.

For the removal of the faucial tonsils the guillotine tonsillotome is the accepted instrument. For pharyngeal hypertrophy Phillips[7] states that a few years ago nearly all operators in the country used the Hooper modification of the Lowenburg forceps. Valuable improvements have been made in the forceps by Brandegee and others. At present the Gottstein curette or some modification is most in use. Many make use preferably of the finger nail. The adenoid knife, such as used by Jansen and others in the clinics in Berlin, is a simple instrument, comparable in its action to the Mackenzie tonsillotome, and when of proper size for the case at hand, and used with sufficient force, will usually remove the pharyngeal tonsil at a single stroke. The danger from hemorrhage in these operations is small. Sajous[8] has seen but two serious hemorrhages from removal of faucial tonsils, neither of them fatal. The series from which J. Wright collected thirty-one cases of bleeding, two of them fatal, numbered probably one hundred thousand operations, according to Roe.[2]

Although cases resulting fatally from hemorrhage following operation on the third tonsil have been reported by Kenefick and others, the total of all operations from which these cases have been collected would, no doubt, show a similarly low proportion. Würdeman[9] reports that in the several hundred operations he has done there has been no case giving rise to any anxiety on that account.

I believe that the removal of these structures is best performed without an anæsthetic. The danger of inhalation of blood-clot, which Delavan says is by no means imaginary, must be increased by anæsthesia. Newcomb[3] gives as his experience that "tonsillotomy may be more satisfactorily accomplished without anæsthesia than with it." Hinckel[10] gives a list of eighteen deaths under chloroform in these cases, and concludes that "the general use of chloroform in the operation for hypertrophied tonsils or naso-pharyngeal adenoids is inadmissible." Cocaine is not without its danger, does not greatly diminish the pain, and in the case of children is likely to give alarm.

The pain attendant upon removal of these lymphoid masses is frequently borne by children without protest. Once removed, though there is a certain danger of recurrence, estimated by Douglass[11] as three in one hundred in the course of one year, no fear need be entertained from loss of the tissues. Freeman,[2] while considering that the pharyngeal tonsil is a normal structure, and that its function as a germinating centre for leucocytes is often overlooked, admits that "its enlargement interferes so markedly with the vital processes of free nasal breathing and normal ventilation of the ears that its physiological functions should not weigh against such important considerations when damage is threatened by its presence."

Hypertrophy of the lingual tonsil, occurring in the adult, may be removed under cocaine anæsthesia with the galvano-cautery.

## Progress of Medical Science.

**The Protracted and Chronic Forms of Influenza.**—Prof. Nil Filatow (*Deutsche Mediz.-Zeitung*, August 28th) states that under the name of protracted influenza are understood such cases as last a considerable length of time, that is to say, those whose febrile stage is of much longer duration than the average case. The protracted form shows itself more frequently without catarrhal symptoms, but rather with fever which progresses for a long time without intermission; in other instances the chronic form shows itself by severe but short (one to three days' duration) attacks of influenza, which recur at intervals of months or perhaps years. In the first form, which is the more frequent, the history is somewhat as follows: In a certain family a febrile disease occurs which to all appearances is influenza; this affects young and old. In one, the disease is characterized only by general weakness, in another cough and coryza are added; sooner or later all, with the exception of one or two, recover. Despite the disappearance of the cough, complete recovery does not occur; loss of appetite and general weakness remain, and these increase at certain periods of the day, for example, from 12 to 3 P.M. At this time, headache and chilly sensations sometimes occur, and the weakness reaches such a height that the patients gladly seek their bed. Two to four hours afterward, this increase in the symptoms disappears with more or less sweating, whereupon the patient at once assumes his previous condition of a relatively well person. The temperature at this time shows a slight increase, whereas during the exacerbation it rises to 38°–38.5° C., but after this it does not fall to normal. In general, the disease resembles an atypical malaria, but despite the many weeks of fever the spleen remains of normal size. The plasmodia are not found in the blood, and quinine given per os or subcutaneously has no visible effect upon the course of the disease. The main symptom is the fever, for which no local cause can be found. This fever is characterized by two points: (1) It lasts a considerable length of time—from six weeks to three months and longer; (2) the fever rises very little or not at all, and yet the patients are febrile; this is seen by the malaise and weakness, which reach their climax at a certain period of the day; sometimes little chills are complained of, and more frequently sweating is observed. As far as the second form is concerned, it may be said that the individual attacks, which are characteristic of the disease, do not differ materially from the ordinary attacks of acute influenza; in some cases the temperature rises rapidly to 40° C., and even higher; in others it remains perfectly normal. Catarrh of the respiratory apparatus is often absent, as are the initial chill and final perspiration. The attack lasts from one to three days. The diagnosis, in cases in which the influenza occurs epidemically in certain families, is not difficult. The diagnosis of individual cases rests upon the character of the fever (moderate rise, paroxysmal course), its duration, and upon the possibility of excluding other causes for its presence. At the beginning, typhoid and malaria must be thought of and later miliary tuberculosis. As to typhoid, a negative Widal and diazo reaction are of great significance. The absence of plasmodia speaks against malaria, it is true, yet is not absolute, since in protracted malarias

which have been treated with quinine they are not infrequently wanting. If, however, the etiology is not clear, the treatment with quinine and arsenic (particularly subcutaneously) is not productive of good results, and the course of the disease is not characteristic of a typical malaria, then the absence of the plasmodia may be of great importance in the diagnosis. In cases of chronic influenza which are characterized by short recurrent febrile attacks, the absence of enlarged spleen, of malarial cachexia, and the fact that the attack lasts the same length of time whether the patient receives quinine or not, speaks directly against malaria. If the attack lasts two or three days, the temperature remains high during the entire time, and the characteristic febrile malarial periods are wanting. At times it is very difficult to exclude miliary tuberculosis, particularly when the chronic form of influenza attacks one with a tuberculous family history, or one who is predisposed to tuberculosis (a scrofulous subject with a history of repeated attacks of bronchitis). The disease begins with catarrhal symptoms and the cough continues; it then becomes very difficult to decide whether we have a protracted influenza or a tuberculosis. If the patient is not predisposed to tuberculosis, if the influenza runs its course without catarrhal symptoms, if during the entire time the temperature reaches only a moderate height and does not remit, and particularly if the same fever exists in other members of the family, then it is not difficult to exclude acute tuberculosis. The prognosis is for the most part good, but the duration of the disease cannot be foreseen. Inasmuch as the disease might be complicated with tuberculosis, pneumonia, and pleurisy, an absolutely good prognosis must be cautiously given.

**Effect of Gout upon the Heart.**—Dr. Karl Grube (*Deutsche Medizinal-Zeitung*, July) says that gout may affect the heart: (1) By giving rise to an organic affection of the coronary arteries and thereby a disturbance of cardiac nutrition; (2) by causing chronic granular kidney with its accompanying cardiac changes; (3) by a direct influence of the poison—which must be recognized as uric acid at present—upon the nervous apparatus of the heart.

**Treatment of Phlegmasia Alba Dolens.**—Professor Pinard (*Bull. Méd.*, 38, 1899) summarizes the curative treatment as follows: (1) Immobilization of the limb in an obliquely inclined position. (2) Alleviation of the pain with morphine if necessary. (3) Injection of antistreptococcic serum as long as the fever continues. (4) Wrapping the limb in cotton saturated with ammoniated chloral hydrate until an eruption appears. (5) Rest in bed for one month after the last trace of elevated temperature due to the phlegmasia has disappeared. (6) Wearing an elastic stocking or underdrawers from the moment the bed is left. The prophylactic treatment consists of: (*a*) the most careful antisepsis during labor, particularly in women predisposed to albuminuria and hemorrhage; (*b*) preventive injections of antistreptococcic serum in women who have suffered from phlegmasia during a previous confinement, or in those in whose family the condition is hereditary, so to speak.

**Bremer's Reaction of the Blood in Diabetes Mellitus.**—Carl Hartwig (*Deutsche Medizinal-Zeitung*, September 18th) as the result of observation concludes as follows: (1) Bremer's reaction is found constantly in diabetes mellitus. Whereas Bremer states that the characteristic color reaction remains even after the disappearance of the sugar, it was found that in the latter instances the color reaction was that of normal blood. Even in alimentary glycosuria Bremer's reaction occurs. (2) This reaction occurs in other conditions as well without sufficient explanation. Thus in three instances of leukæmia the first specimen of blood stained normally, the second like that of diabetes. In three instances of Basedow's disease three gave a normal, one a Bremer's reaction. (3) That the reaction is connected with the hæmoglobin, that is, with its chemical composition. (4) That the cane sugar is certainly a cause of the reaction; that other similar changes in the hæmoglobin could give rise to the conditions is at present very questionable, though not unlikely. (5) The concentration of glucose which is necessary to produce the reaction with pure hæmoglobin is 0.15 to 0.2 per cent.

**The Treatment of Pulmonary Tuberculosis with Camphorated Oil.**—Von Criegern (*Berliner klinische Wochenschrift*, October 23, 1899, p. 939) reports the results of his experience in the treatment of pulmonary tuberculosis among dispensary patients with camphorated oil. Cases of uncomplicated tuberculosis, that is, unattended with ulceration, were uninfluenced by the treatment. In cases with ulceration complicated by hæmoptysis it appeared as though the treatment rather predisposed to the occurrence of the hemorrhage. In cases with cavities, however, the treatment proved distinctly useful. Great symptomatic relief was afforded in cases in the last stages of the disease. The presence of nephritis is a contraindication to the employment of the treatment. Subcutaneous injection of camphorated oil is painful, and the preparation is too irritating to be administered by the mouth, but made into an emulsion with yolk of egg it can be readily given by the rectum as an enema.

**Value of the Tuberculin Test in the Diagnosis of Tuberculosis.**—Edward O. Otis (*Journal of the American Medical Association*, October 28th) summarized an article on this subject as follows: (1) The tuberculin test indicates tuberculosis by a general reaction before it can be detected by other methods, except the *x*-ray, in a large majority of cases, with a dose of from 5 to 10 mgm. of Koch's original tuberculin. (2) No injurious results occur from the use of tuberculin in these cases. (3) Proved tuberculosis in a more or less advanced stage may fail to give the general reaction from doses of from 10 to 12 mgm. (4) Syphilis gives the reaction in an undetermined proportion of cases. (5) There is a dose, undetermined, at which a non-tuberculous person may react or simulate a reaction. (6) The reaction may be deferred from six to twenty-four hours. As rules to be observed in making the test: (1) Always use the same tuberculin of a standard strength. (2) Use aseptic precautions in giving the injections. (3) Make the injections deep into the muscles of the back, arm, or leg. (4) Keep a two, three, or four hourly chart of the temperature, if possible, beginning twenty-four hours before the injection. (5) Allow several days to elapse before repeating the test. (6) In early cases depend on general reaction; in late cases, if the general health fails, carefully look for the local reaction.

**Action of Anhalonium Lewinii (Mescal Button).**—Of recent years the mescal button has excited some degree of interest mainly because of the pleasurable visual hallucinations that it has excited. W. E. Dixon (*Journal of Physiology*, vol. xxv., No. 1, p. 69) has studied the action of the various alkaloids, first isolated by Heffter. These are anhalonine and anhalonidine, both having the same formula, being isomeric; lophophorine, belonging to the same series, differing only by the addition of a $CH_2$ group; and mezcaline, which is closely allied, especially physiologically, to

anhalonine, though structurally it differs somewhat. The animals experimented upon were mainly dogs. The differences between the alkaloids were as follows: Anhalonine and anhalonidine have an action which seems to be the same in each case, but lophophorine, while behaving very similar to these, is probably about twice as active. It has greater nerve-irritating powers, since muscular twitchings and the reflexes are more markedly heightened following its use. Mezcaline, while agreeing precisely with the other alkaloids as regards cardiac and respiratory action, appeared more effective in the production of color visions. Respiratory depression is manifest. This is apt to persist as an after-effect. Circulatory depression is less than respiratory, though it is also present. Nausea is generally present after a large dose, but vomiting is rare. Small doses rarely produce unpleasant after-effects. It seems that mescal acts differently from any other substance, although in its isolated properties it resembles many. Cannabis indica, which at first it was thought most closely to resemble, differs from it in the delusions of merriment and in its hypnotic effect, whereas "mescal" never rises to merriment, but rather to a condition of ideal content, and produces wakefulness. It is allied to strychnine by its effect on the brain and cord, though in this respect its action is more cerebral than spinal. Opisthotenos never occurs with mescal. In its action on nerve fibres it resembles the paralyzing action of nicotine. In some respects it acts as a stimulant, similar to digitalis and cocaine, and its use in therapeutics seems from Dixon's investigations to be fraught with much promise. Its gentle stimulating effect indicates it in diseases of the nervous system, and more especially by its diminution of the kinæsthetic sensations, it is called for in melancholia. Further, its effect on slowing the heart by a direct action on the heart muscle, and in small doses increasing the force of the beat, may be of some use in circulatory therapeutics.

**The Treatment of Goitre.**—Bouffleur (*Medicine*, November, 1899, p. 881) submits the following conclusions, based upon existing knowledge of goitre: Successful treatment depends upon accurate and early diagnosis of the nature of the goitre. Struma should be treated by the internal use of iodine or thyroid extract, and the parenchymatous injection of iodoform or carbolic acid. If these fail, either enucleation or partial thyroidectomy is indicated. Adenoma should be treated by enucleation if the tumor is small, and by partial thyroidectomy if large. Cysts should be treated by evacuation and injection of carbolic-acid solution or iodoform emulsion. If this fails, the cysts should be enucleated. Sarcoma and carcinoma should be treated by complete removal of the thyroid gland, with subsequent administration of thyroid extract. The treatment of exophthalmic goitre is generally unsatisfactory, and at present surgical measures promise the best results. Undifferentiated goitre may be treated with thyroid extract and iodine, but parenchymatous injections, and if necessary operative treatment, should be employed early. The surgical treatment of all varieties of chronic goitre is, generally speaking, the most successful and most satisfactory.

**The Pathogenesis of Yeasts.**—It is daily becoming more apparent that other of the lower forms of vegetable life than bacteria are the cause of disease in man and animals. Since the recent work of many observers on the parasite of carcinoma the yeasts have come to occupy an important rôle in the eyes of bacteriologists. Recent work by M. P. Uesczadimento (*Centralblatt für Bakteriologie und Parasitenkunde*, 1899, vol. xxv., 2, 3, p. 55 *et seq.*) shows that if pure cultures of yeast be injected into rats, mice, guinea-pigs, dogs, and rabbits, there result a number of pathological processes, most of which cause the death of the animal in from eight to twelve days. Infection of the peritoneum in rats and guinea-pigs produces a peritonitis with productive inflammation of the omentum. In the guinea-pig pus develops, which gives pure cultures of the yeast on subsequent cultivation. Abscesses may also develop as a result of subcutaneous injections of pure cultures. The individual yeast cells undergo many morphological changes; many involution forms are apparent, and a number of forms which closely resemble those recently described as inclusions in the cells of carcinomata were observed by the writer. It seems probable from the author's work that yeast cells play a much more important rôle in pus formations than has hitherto been supposed.

**Uncontrollable Vomiting, due to Gastric Obstruction by the Pressure of an Aneurism, Relieved by Cœliotomy and Manipulation.**—Ewart and Jaffrey (*Lancet*, October 28, 1899, p. 1155) report the case of a married woman, forty-nine years old, who was thought to be suffering from intestinal obstruction, with constipation and persistent vomiting of a week's duration. The patient had been abstemious, but had suffered from jaundice in childhood and from rheumatism at the age of forty. Nine months before coming under observation she had passed through a prolonged attack of vomiting and constipation. For a year previously there had been morning vomiting after taking tea. The patient was wasted and prostrate. The pulse was large and tense, and the radial artery tortuous. The costal arch was depressed, and the abdomen flat, tender, and tense. A pulsating mass, with a systolic bruit and thrill, could be felt indistinctly in the left epigastric and umbilical regions. The vomiting of all ingesta and even of plain water persisting in spite of the ordinary measures of treatment and diet, malignant disease or ulcer of the stomach was suspected. Exploratory cœliotomy was decided upon, and an incision from four to five inches long was made above the umbilicus. The stomach presented in the wound, and on examination it was found to be quite healthy though dilated. Its walls did not appear to be materially thinned. The colon appeared to be normal. An attempt to press some of the fluid present in the stomach into the duodenum was unsuccessful, and on further examination the swelling that had been felt through the abdominal wall proved to be a large fusiform aneurism of the abdominal aorta. This commenced about half an inch below the aortic opening of the diaphragm and extended to the level of the umbilicus. The pyloric extremity of the stomach was flattened over the convex surface of the aneurism, so much so as to cause obstruction to the passage of the contents of the stomach into the duodenum. This seemed to be partly due to the weight of the dilated stomach and its contents and of the colon and the omentum. As much as possible of the stomach was pulled over to the right side of the aneurism so as to relieve the pressure, and as the stomach seemed inclined to remain in its new position it was not thought necessary to fix it in any way. The patient rapidly recovered from the operation. The wound was dressed with dry cyanide gauze, and the sutures were removed on the eighth day. For several days there was slight vomiting, in connection with nausea excited by the smell of brandy, but the alarming symptoms disappeared, and the patient slowly improved, and began to take solid food, and to walk for short distances. She complained of burning sensations in the epigastrium, and had general hyperæsthesia of the abdomen, but the pulsating mass was less easily felt, no doubt in consequence of the fundus of the stomach being placed between the aneurism and the abdominal wall.

MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

New York, November 25, 1899.

## INFLAMMATION OF THE PONS VAROLII.

INFLAMMATION of the brain may be excited by traumatism, by extension from adjacent disease or, through the blood-vessels, from remote disease, and by general infectious processes. It may be purulent or non-suppurative, and it may involve principally either the white or the gray matter. There are certain points of analogy between inflammation of the brain and inflammation of the spinal cord, and both brain and cord may be involved conjointly.

We may thus have in combination myelitis and encephalitis, or poliomyelitis and polio-encephalitis. The symptoms will vary in accordance with the structures attacked. Thus, the cortex may suffer most, or the basal ganglia, or the third ventricle, or finally the nuclei in the pons and medulla, and the symptoms will naturally vary in accordance with the localization and the extent of the lesions. The onset may be acute, with convulsions and loss of consciousness, followed by paralysis of varying distribution, cerebral suffering equally with spinal nerves. On the other hand, the symptoms may set in insidiously, and we may have presented the clinical picture of progressive muscular atrophy, progressive bulbar paralysis, ophthalmoplegia, alone or in varying combination. It is not impossible, further, that in some cases multiple foci of inflammation have preceded cerebrospinal (insular) sclerosis. A case of so-called polio-encephalitis inferior presenting some unusual features has recently been reported by Oppenheim.[1]

The patient was a girl, nineteen years old, who gave a history of having been seized with loss of consciousness and convulsions, lasting several days, at the age of one year. Subsequently the left side of the face was found paralyzed; the left eye remained open, and the mouth was drawn toward the right. It was thought also that the right eye was turned inward. Gradual improvement followed, and the patient learned to close the eye, and the mouth in time became drawn toward the left. As the girl grew up, she became annoyed by twitching and tremor of the muscles of the left side of the mouth and chin, and by a sensation as if the upper lip was too thick and too hard, and there was also some embarrassment of speech. The face presented a peculiar indefinable asymmetry; there was slight flattening of the left side of the mouth and chin, while the contour of the muscles of the left side of the chin, especially the quadratus menti, was well marked in consequence of constant tension. The left angle of the mouth was lower than the right, and active movements of the lower part of the face were more marked on the right than on the left. The orbicularis palpebrarum was equally active on both sides, although the left eye was opened less quickly than the right, and the frontal furrow was wanting on the left. Almost constant fibrillary twitching was visible in the muscles of the chin and lower lip of the left side, with tic-like movements occurring synchronously with closure of the eyes. The tongue, when protruded, deviated somewhat toward the left, its raphe forming a concavity toward the left posteriorly, and toward the right anteriorly, the tip being directed toward the left. The left half of the tongue was thinner and smaller than the right, presenting depressions and elevations, and fibrillary tremor. On the floor of the mouth the tongue deviated somewhat toward the right, so that its tip was directed toward the right half of the lower jaw. The raphe of the floor of the mouth passed obliquely from in front and the left toward the right and behind. The uvula, at rest, was deflected slightly toward the left, but in phonation no difference in the motility of the two sides was discernible. In speaking, the left omohyoid became especially prominent. Electric examination disclosed quantitative diminution in the irritability of the left facial nerve on both direct and indirect stimulation with both faradic and galvanic currents. The diminution was most marked in the platysma myoides and particularly on the left. The contractions on direct stimulation with the constant current were lightning-like on both sides. On stimulation of the right facial nerve with weak currents, a contraction occurred in the muscles of the left side of the lip and chin, and with such current strengths as induced in the corresponding muscles of the right side slight if any contraction, and which were entirely without effect on direct stimulation of the muscles and nerves of the left side. This crossed, or contralateral, contraction occurred only in those portions of the muscles in proximity to the median line; it appeared also in a portion of the muscles of the upper lip, and in the corrugators of the brow. Closure of the constant current on the outside of the neck, with either cathode or anode, induced movements of deglutition, and with feebler currents on the left than on the right. The knee jerk and the Achilles tendon jerk were more pronounced on the right than on the left. A blow on the right patellar tendon caused at times a contraction of the left tendon, but the opposite condition was not present.

The lesion in this case was believed to be cerebral, on account of the acute onset in childhood with convulsions, loss of consciousness, followed by paralysis of the left facial and hypoglossal nerves, with recession of the symptoms and degeneration of the affected muscles. That it was not cortical in situation seemed to be indicated by the fact that the upper branch of the facial nerve was involved, and by the occurrence of degenerative changes. Further, the reflexes were

[1] Berliner klinische Wochenschrift, No. 29, 1899.

increased on the side of the body opposite to that affected by the paralysis. That it was nuclear (bulbar) rather than peripheral, was rendered probable by the acute onset, and the occurrence of convulsions. It appeared that the muscles most needed and most exercised recovered in greatest degree. The reaction of some of the muscles of the left side of the face close to the median line to currents not affecting even the healthy right side is considered due to innervation of the facial muscles of the left side close to the middle line by the facial nerve of the opposite side, as a result, perhaps, of the growth of the branches of the nerve.

## THE EVOLUTION OF THE BEDROOM AND BEDSTEAD IN ENGLAND.

The late Lawson Tait was a man of many parts, and if he could not wield the pen so skilfully as the knife, at any rate as a writer he was by no means to be despised. There can be small room for doubt at least that his opponents held this opinion. Unfortunately a great deal of his writing, as his speaking, was of an aggressive and polemical character. However, when he chose he could write in a quiet, fascinating style, especially on matters concerning social reform and hygiene. Perhaps the last article contributed by him was on the "Hygiene of the Bedroom and Bedstead," which has appeared in several British and American medical journals, and, if such a term is allowable, may be regarded as a domestic classic. It traces almost lovingly and in language picturesquely descriptive the evolution of the bedroom and of that now necessary article of furniture in Great Britain, the bedstead itself. It tells us that in the days of the cave-dwellers, and through the various stages of savage and nomad life, the dwelling space was used for all purposes in common, and that it was not until the wandering hunter had, so to speak, settled down that he saw the advantage of setting aside a portion of his dwelling for sleeping purposes. After a brief reference to the times of the Briton in Britain, the story brings us to the Norman era in that country, and shows us that the Norman—albeit his castle might be grim and forbidding outwardly—yet had a very fair notion of what constitutes a comfortable bedroom and bedstead, as well as more than rudimentary ideas on effective hygiene. The walls of their castles were thick and solid, thus securing a fair uniformity of temperature, while the downfall of cold air was modified by the hangings of tapestry. For their bedsteads there was no need of hangings. We are told that the Saxon farmer, on the contrary, had perforce to live under very different conditions. His houses were of wood, and as he was no adept at carpentering the doors and windows were ill-fitting, and draughts were in consequence the rule rather than the exception. Hence was evolved that abomination of abominations, the four-poster bed, or, as Lawson Tait preferred to put it, "A small apartment was constructed inside the bed room in the shape of a huge four-poster hung round with curtains, into which a whole family must have crowded, possibly with the addition of occasional visitors." It is shown how strenuously the conservative Britisher clung to his time-honored four-poster until the fifties, when, as Tait satirically said, the dawn of domestic sanitation as we know it occurred, and was not fully appreciated till well on in the seventies. A pathetic picture is drawn of the trials attending the unwary visitor to London even in the seventies, when it was the rule to have vermin in all bedsteads used by the public, and bugs were made the subject of chronic jokes in all humorous writings and pantomimes. The story goes on to tell that the first step in the right direction was the introduction of metallic bedsteads, and Tait related that he remembered very well the furore of indignation with which they were met—for nothing annoys an Englishman so much as any interference with his personal habits or belongings. It is related, however, that finally all scruples were overcome, and that at last metal bedsteads have had their way. Thus is traced in brief the evolution of the bedstead in Great Britain.

## IS COMMERCIALISM GROWING?

Is it becoming necessary for a patient to ask himself whether a scheme may not be hatching when the family physician advises the consultation of a surgeon or specialist. It would be sad indeed if the general public comes to believe that the majority of physicians are constantly working in their own interests, from mercenary motives, and entering into conspiracies with still more unscrupulous persons to "do" the unfortunate sufferer.

The effrontery of certain quacks and those who are so short-sighted as to imitate their methods has led to the belief that much more is being done in the commercial spirit, and under the division-of-fee policy, than is actually the case. Those in the reputable ranks who publicly defend such a course of action are few indeed. Still there must be a certain number of supposedly reputable physicians who enter into it in a silent-partner sort of way, since financial propositions from those possessing a secret process or unusual knowledge and facilities for effecting rapid cures seem to abound. These persons would scarcely persist in bidding for support from the honorable portion of the medical profession, unless there were some returns.

The proprietor of a sanatorium in this city has just issued a circular offering a discount of twenty per cent. on collections to physicians referring patients for operation. In Chicago a woman who cures cancer by a secret method appeals to the profession by an offer of twenty-five per cent. on all cases that pay over $300. She says: "Let me know when the patient comes how much he is able to pay, and about what he is safely considered worth." The enterprising lady evidently does not believe in working a man for all he is worth unless she knows approximately for what amount she is working. In following the excellent advice given to surgeons back in the sixteenth century by Guy de Chanliac, she has omitted such distasteful words as

"merciful" and "moderation." This writer of four centuries ago said: "Let the surgeon be chaste, pitiful, merciful; not covetous or extortionate, but rather let him take his wages in moderation, according to his work and the wealth of his patient and the severity of the disease, and his own worth."

Bids for patronage "on shares" would seem of late to have increased in number and in brazen effrontery. Any one who might fear falling to this form of bribery in an unguarded moment of weakness should strengthen his manhood by reading the following extract from the by-laws just adopted by the St. Louis Medical Society:

"Publicly boasting of cures or remedies, or adducing certificates of skill or success, or paying or offering any salary, bribe, or commission in return for patients procured, or accepting the same, or employing others to do any of these things, shall, among other things, be considered gross misconduct."

## CULTURE IN THE MEDICAL PROFESSION.

The writer of an article in a recent number of *The Lancet* was somewhat severely "hauled over the coals" by some of his medical contemporaries for asserting that "the great majority of those young men who elect to follow medicine as a profession are by no means distinguished by culture or polish, but are for the most part drawn from the lower middle classes." This expression of opinion did not meet with general approbation, and it was pointed out that the type of medical student depicted so ably in the person of Bob Sawyer and Ben Allen by Dickens in the "Pickwick Papers," no longer exists, and that the rowdy, saloon-haunting embryo physician is almost as extinct as the dodo. We take it, however, that this was not intended to be the interpretation placed upon the offending editorial. Doubtless the meaning intended to be conveyed by *The Lancet* scribe was that the medical profession does not hold out sufficient inducements for the "*jeunesse dorée*" of Great Britain either in the way of social position or so far as pecuniary advantages are concerned. This view of the situation is probably correct. In no other profession are the prizes to be gained or the value placed upon the ordinary everyday labors so incommensurate with the difficulties to be overcome in gaining an entrance into the ranks as in that of the medical profession. The work to be done in order to become a minister is child's play in comparison; and the same may be said, although in a lesser degree, in regard to the legal profession. A writer in the September edition of *The Medical Magazine* agrees with *The Lancet* that the medical profession in Great Britain does not attract the young men who have received their education at the large fashionable schools, as Eton and Harrow, and furthermore points out that there is an increasing dearth of culture among the leading practitioners of the day, and that the old scholarly physician of forty years ago is almost extinct. This same writer goes on to say: "I do not want to run down my professional brethren, for harder-working, keener, kinder-hearted, and more philanthropic men do not exist; but their lack of general information is often deplorable. The practitioner becomes keen, self-reliant, full of resource, but he often becomes rough and too frequently coarse." Whether a medical man needs culture, or whether it is better that all his time should be spent in mastering his profession, is a point concerning which there is much divergence of opinion. Lawson Tait, who in everything was original, suggested that part of the curriculum of a medical student should consist of working as a blacksmith or carpenter for the sake of training the eye and acquiring dexterity with the fingers. On the contrary, many shining lights of the healing fraternity hold that a degree in arts should be a "*sine qua non*" for those who intend to follow the doctor's calling. For the man whose aim it is to practise in a large town and among the educated classes, there can be no doubt that a liberal education will at any rate be no drawback, while on the other hand the man whose lot is cast "far from the madding crowd" will probably do better to spend his time in thoroughly learning all the practical details of his profession rather than in endeavoring to gain a smattering of Greek and Latin.

## News of the Week.

**Smallpox** is reported to have broken out at Cape Town, the disease having been brought by refugees from the Transvaal.

**Fécondité.**—M. Zola may be interested to learn of a woman in Mountain Top, Pa., who recently gave birth to her twenty-fifth child, a strong and healthy boy. He has twenty-one brothers and sisters living, three of the family having died.

**Dr. Pepper's Estate.**—The estate of the late Dr. William Pepper, of Philadelphia, formerly provost of the University of Pennsylvania, has been appraised at $670,888. This includes a life insurance policy of $50,000.

**Marriage of a Medical Missionary.**—The Hong Kong correspondent of the London *Mail* says there is indignation in missionary circles at Canton over the approaching wedding of an American female medical missionary to a Chinese coolie, who was formerly employed by her as a cook.

**A Label for Doctors.**—The trustees of the American Medical Association have adopted an official button with which the members are requested to label themselves. It is of gold with red, white, and blue enamel. In the centre is a lance-pointed cross, the ends of which point to the word MAMA, which is probably not a term of endearment, but is formed of the initial letters of "Member of the American Medical Association."

**Embalmed Beef in England.**—According to London despatches to the daily press much indignation has been aroused in England by the bad quality of

the food supplies furnished by the contractors engaged to fit out the transports carrying troops to the Cape. One vessel last week had to be delayed twenty-four hours, owing to the fact that fifteen thousand pounds of rotten colonial beef and mutton had to be replaced. All the meat was taken out of the ship and dumped overboard at sea.

**Errata.**—In the report of Dr. Smith's paper on pneumonia, in the RECORD for November 18th, p. 757, first column, line twenty-seven, for digitalin read digitalein, and in line twenty-nine for *rather* read *less*. This last correction reverses the meaning of the passage.

**An Anti-Vaccination Story Spoiled.**—Two children died not long ago, one at Brewster's and one at Geneva in this State. The deaths occurred after vaccination, and were said by the anti-vaccinationists to have been caused directly by this operation. The State board of health has, however, investigated the cases, and finds that death in each instance was due to the neglect, ignorance, and filthy habits of the parents, and failure on their part to carry out the instructions of the physicians who performed the vaccination. One child died of tetanus, and the other of septicæmia. The parents of one of the children failed to remove the soiled bandage from the arm, and kept adding others until no less than seven were counted.

**The Plague** continues in Portugal, two or three deaths a day being reported at Oporto. The death of the director of the Bacteriological Institute at Lisbon from plague is announced. Santos, Brazil, has become a new distributing centre for the disease. The captain of the Austrian Lloyd steamship *Bernice*, from Santos for Trieste, reported from the Cape Verde Islands, on November 5th, that he had the plague on board and that three of the persons attacked had died. The Lamport and Holt Line steamer, *J. W. Taylor*, also from Santos, arrived in New York on November 18th with two cases of plague on board. The sufferers are the captain and the cook; the disease in them is mild, and it is believed both will recover. There had been no deaths during the voyage. The ship left Santos with a cargo of coffee on October 24th and sailed direct for this port. She had on board twenty-nine persons. On November 1st the steward was taken ill with headache and high fever and the symptoms of bubonic plague soon developed. The man, who was twenty-two years old, had been in hospital at Santos for two weeks with what was diagnosed as eczema, but was sufficiently improved to be discharged just before his ship sailed. He was cared for by the captain and the cook, both of whom took the disease. The passengers and crew will be detained at quarantine for some time, and the ship will be disinfected. It is probable that she will not be allowed to come to her dock, lest some infected rats escape and so carry the disease into the city. In this connection the following report from United States Consul Heenan, of Odessa, is interesting. It was printed in a recent bulletin of the Marine Hospital service, being taken from advance sheets of Consular Reports, No. 549. He writes under date of August 28, 1899: "I saw the other day a curious device attached to the mooring rope or cable of a steamer which was loading at this port. The cable was run through a piece of iron pipe about a foot in length, and welded on the end of the pipe was a flange or funnel which looked like the end of a trumpet, with the wide end facing the ship. The iron pipe was stuffed with oakum, to prevent it from slipping and also to prevent rats from passing through it. This novel construction was quite close to the ship. On inquiring what purpose this device served, I was informed that the Russian authorities furnished these appliances and obliged all ships to use them whenever they came from a port infected with the plague, in order to prevent the rats on the ship from coming on shore. It is generally conceded that the plague has been carried and spread by rats which have left ships coming from infected ports. It is known that rats make use of the cable to come on shore, and this iron pipe with its funnel-shaped arrangement was employed to prevent such visits, if possible. These devices were attached to each cable by which the ship is moored. In addition to this precaution, the master of the ship is obliged to take down his loading stages every night and erect them again the following morning, in order to prevent the rats from coming on shore during the night. I do not know whether this device is known to our sanitary authorities, and I send this description of it in the hope that it may be of service."

**A Medical Consultation Bureau.**—It has been proposed to establish in Birmingham, England, an institute where a consultant's opinion can be obtained for 10*s.* 6*d.*, or just half the regular rate. The medical men of the city have held a meeting and passed resolutions that, with the exception of the senior and most prominent consultants, all the others were willing to visit the poor in consultation for the same fee of half a guinea. This has had no effect upon the promoters of the scheme, however. They propose to pay two consultants, a physician and a surgeon, £500 a year each, and expect to make quite a handsome profit out of the undertaking.

**The Medical and Chirurgical Faculty of Maryland.**—At the semi-annual meeting of the Medical and Chirurgical Faculty of Maryland, held at Westminster, November 14th, Dr. William Osler, of Baltimore, read a paper on "The Home Treatment of Consumption," in which he said that ninety-five per cent. of the sufferers from tuberculosis seen by physicians were unable to afford treatment away from their homes in the cities, therefore as much as possible should be done to promote a cure in their own homes. He said that a life in the open air had long been known to be the means of the arrest and sometimes of the cure of the disease, and this might be attained even in cities, by arranging a couch for the patient, with plenty of blankets, on a porch, under a shed, or even in a sunny room with wide-open windows. From two hours after sunrise to an hour before sunset the patient, well wrapped up, might sit in the open air even on the

coldest days. The diet, he said, was extremely important, but the treatment varied with each patient. As much nourishing food as possible should be taken, particularly raw eggs three times daily. The number could be increased until the patient might eat as many as two dozen a day. He said that little medicine was required, and the remedies might be placed under three heads: first, those assisting the digestion; second, those for promoting general nutrition, such as cod-liver oil, hypophosphites, and creosote; and third, remedies for relieving cough, pain, and night sweats. Dr. Simon Flexner, formerly of the Johns Hopkins University, now of the University of Pennsylvania, gave an account of investigations in the Philippines, made by himself and Dr. L. F. Barker, of the diseases prevalent there. Their work was carried on among the American soldiers and the natives, the latter being studied for beri-beri, also leprosy and skin diseases. One of the commonest forms of skin disease is an itch or ringworm, which is communicated by the washerwomen, who use only cold water for washing clothes. Dr. Flexner exhibited tubes in which were grown colonies of the germ which is supposed to produce tropical dysentery. Dr. Barker described the three forms of beri-beri and showed photographs of the natives who suffered with the disease at Cavite.

**A Case of Anthrax.**—A 'longshoreman died a few days ago in the Long Island College Hospital of anthrax. He had been engaged in unloading hides from a vessel, and it is supposed that he became infected in that way.

**A Gift to the Red Cross Society.**—The Central Red Cross Society of Geneva has received from the French Red Cross Society, through its president, the Duke of Auerstadt, the gift of a complete equipment of medical appliances, instruments, etc., sufficient for two field hospitals.

**A New York Graduate Refused a License in Nebraska.**—At a meeting of the Nebraska State board of health at Omaha on November 3d, the application of a recent graduate of the University and Bellevue Hospital Medical College of this city for a license to practise medicine was refused. The applicant attended two courses in the Creighton College at Omaha, the last in 1897–98. The Nebraska schools all require four years' attendance before graduation, but the student came to New York and graduated in the spring of 1899 on one additional course of lectures. As the Nebraska statute requires four courses before a certificate can be issued, the applicant was refused.

**The Rank of the Naval Pharmacist.**—Until very recently all pharmacists in the United States navy have been enlisted men, the highest rank to which they could attain being that of chief petty officer. The recent naval personnel act created twenty-five warrant pharmacists. A warrant officer in the navy ranks next below the commissioned officer, but much above the petty officer. A warrant, like a commission, carries with it many privileges; it makes its possessor a responsible party in the eyes of naval regulations; it cannot be taken away at the whim or caprice of a superior without due process of law; and it is a life guarantee that during good behavior the remuneration connected with it shall continue. The warrant officers have comfortable quarters, rooms to themselves to sleep in, and a mess room, and servants are assigned to them. Measures have been taken to petition Congress to raise all the naval pharmacists to the rank of warrant officer, after they have passed a satisfactory examination. The request would certainly appear to be a reasonable one.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending November 18, 1899. November 10th.—Medical Director C. J. Cleborne placed on the retired list of officers of the navy from November 10, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service; with the rank and three-fourths the sea pay of the next higher grade under section 11, navy personnel law. Passed Assistant Surgeon L. L. Young placed on the retired list of officers of the navy from November 10, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service. Assistant Surgeon H. E. Odell appointed from November 8, 1899. Assistant Surgeon J. S. Taylor appointed from November 10, 1899. November 11th.—Passed Assistant Surgeon R. G. Brodrick placed on the retired list of officers of the navy from November 11, 1899, under section 1453, Revised Statutes, for incapacity incurred in the line of service. November 15th.—Passed Assistant Surgeon J. C. Rosenbleuth, sick leave extended two months. November 16th.—Passed Assistant Surgeon G. B. Wilson detached from the *Constellation* and ordered to the *Dixie*. Passed Assistant Surgeon R. P. Crandall ordered to the *Constellation*.

**Obituary Notes.**—Dr. William C. McDuffie, of Fayetteville, N. C., died on November 3d at the age of seventy years. He was a graduate of the New York University Medical College in 1855. He was president of the North Carolina State Medical Society in 1885, was chairman of the board of commissioners of Cumberland county, physician for the county poor for a great number of years, and a member of the board of aldermen of Fayetteville.

Dr. Matthew J. Smith, of Jersey City, N. J., died at his home in that city on November 16th. He was born in Jersey City in 1859, and was graduated from the College of Physicians and Surgeons in this city in 1890.

Dr. D. Webster Prentiss, of Washington, D. C., died on November 19th, at the age of fifty-six years. He was a graduate of the Medical Department of the University of Pennsylvania in 1864. Immediately upon graduation he entered the Union army and served on the medical staff until the close of the Civil War. In addition to many medical articles he was the author of a work on the song and game birds of Maryland and the District of Columbia.

## Surgical Suggestions.

"Pigeon-Toeing" is a conservative effort on the part of the child who is rachitic, because it finds that it can best support the weight of the body by turning in the toes. This should not be corrected, for it will take care of itself when the general condition is improved by proper diet, hygienic surroundings, and constitutional treatment.—R. H. Sayre.

**Fissure of the Anus.**—Keep the stools watery and apply ichthyol in its full strength daily; subsequently every second day.—Conitzer.

**Paraphimosis** from a constricting metallic ring can be relieved by applying metallic mercury to the ring until it is disintegrated.—*Cincinnati Lancet-Clinic.*

**Chronic Ulcer of the Leg.**—I have laid down this rule: An ulcer situated above the middle of the leg is syphilitic, regardless of history. I make it a rule to examine the heart, lungs, and kidneys in all cases, as disease of any of these organs interferes with the local treatment. For instance, if the heart is diseased, passive congestion and œdema of the lower extremities are of frequent occurrence. Proper attention, then, to this organ, when compensation is possible, will greatly facilitate getting rid of the ulcer. But simplicity, cleanliness, and the proper time to interfere are the sheet anchors in all cases. But, as to drugs, I have as yet to find one which will equal pure carbolic acid.—John B. Corsiglia, *New York Medical Journal*, March 25th.

**Colles' Fracture.**—In seeking to repair a Colles' fracture every effort should be directed toward: (1) Complete reduction of both fractured radius and dislocated ulna. So essential is this that if successfully accomplished the treatment is usually uncomplicated and the results are all that one could desire. (2) The use of simple but effective means to keep the fragments in apposition and to prevent recurrence of the dislocation of the ulna, care being always taken not to have any undue pressure interfere with the return circulation. (3) Prevention of adhesions of tendons by early passive motion of the fingers, thumb, and wrist. (4) Removal of the mechanical appliances as soon as practicable after the fragments have united.—E. M. Dooley, *Buffalo Medical Journal*, March, 1899.

**Prostatic Enlargements.**—In a personal examination of the prostates of three hundred and sixty men over fifty-five years of age, the large majority being between sixty-five and seventy-five years, I found two hundred and eighty-six, or $75\frac{1}{9}$ per cent., to have very perceptible enlargement of the prostate. In sixty-five, or $18\frac{1}{18}$ per cent., there was urinary disturbance. In fifty-six, or $15\frac{5}{9}$ per cent., the prostate was so large that it could not be outlined by digital examination per rectum. Of these fifty-six, fourteen, or twenty-five per cent., had urinary disturbance constantly, such as dysuria, frequent micturition day and night, rectal and vesical tenesmus, retention at times, with residual urine and cystitis. In two hundred and ten, or $58\frac{1}{3}$ per cent., the prostate was very perceptibly enlarged; forty-three, or twenty per cent., had urinary disturbance of a milder degree than those above mentioned. The right lobe was markedly more enlarged than the left in seven, or $1\frac{7}{18}$ per cent. Of the seven, five, or $71\frac{3}{4}$ per cent., had urinary disturbance. The left lobe was also enlarged in seven, or $1\frac{7}{18}$ per cent., but one had urinary disturbance. The middle lobe was slightly enlarged in five, or $1\frac{7}{18}$ per cent. None complained of vesical distress. The prostate was found to be normal in forty-four, or $12\frac{2}{9}$ per cent. It was atrophied in thirty, or $8\frac{1}{3}$ per cent.; of these thirty, two, or $6\frac{2}{9}$ per cent., had slight enuresis.—George W. Johnson, *International Journal of Surgery*, April.

**Hemorrhage Following the Operative Removal of Adenoid Vegetations.**—H. Cordes (*Deutsche Med.-Zeitung*, No. 25, 1899) states that hemorrhage under such conditions may be due to—(1) General disease, hæmophilia. (2) Cardiac disease, more especially hypertrophy of the left ventricle and arteriosclerosis. The latter conditions apply only to adults and need not be considered in children. (3) Anomalies in the course of the internal carotid. In some cases there exists beneath the posterior pharyngeal wall, on a level with the anterior part of the atlas, a bony crest which by its prominence renders the operation difficult in many cases, and causes alarming hemorrhage if cut. (4) A preparatory application of cocaine may be followed by a severe hemorrhage. (5) Small shreds of vegetations remaining partly attached to the pharynx may give rise to hemorrhage, which ceases when they are removed. (6) Occasionally severe hemorrhage results in females if performed at the time of the menstrual period. (7) In many cases hemorrhage occurs without assignable cause.

**Gall Stones.**—Dr. Joseph Ransohoff, of Cincinnati, considers the etiology, diagnosis, and operative treatment of gall stones (*Journal of the American Medical Association*, September 16th) and feels warranted in submitting the following propositions: (1) The gall stones found in a gall bladder are generally formed together, that is, about one and the same time. Their removal will not be followed by recurrence unless a reinfection of the biliary ways occurs. (2) Cholecystotomy with drainage should be regarded as the normal operation. (3) Save in exceptional cases, the operation should be done at one time. (4) Ideal cholecystotomy or cholecystendesis is not to be recommended. (5) Cholecystectomy is rarely indicated in acute processes. It is more dangerous than cholecystotomy. Since most stones are formed in the gall bladder, cholecystectomy is the more radical operation. It should be reserved for chronic cases in which a restitution of the gall bladder to the normal cannot be expected. (6) Cysticotomy is a safe supplement to incision of the gall bladder for stones of the cystic duct. (7) Choledochotomy with suture and drainage should be considered the routine procedure in common-duct stones. Incision of the duct through the duodenum or from an incision in the loin (Tuffier) will rarely be needed. (8) Cholecystenterostomy has a limited but distinct field of application, *i.e.*, obstruction jaundice from malignant disease or impermeable cicatricial common-duct stenosis.

**Surgical Hints.**—Examine the urine in all cases of pruritus, eczema, gangrenous lesions, furuncles, and anthrax. A certain proportion will show the existence of diabetes.—Remember how frequently constipation aggravates prostatic obstruction. Some prostatic cases are immensely benefited by careful attention to this important detail.—In appendicitis, when the pain keeps on increasing, the pulse remains rapid, and the temperature remains high, delay in operating will soon be considered, and very justly so, as amounting to malpractice.—Slight rises of temperature after an operation, even in cases which give no septic results, warn the surgeon that he is probably erring in some way, and that his methods and material should be pretty thoroughly overhauled.—Make a habit of washing your hands in vinegar or dilute acetic acid before touching septic cases. Slight cuts and abra-

sions, whose presence was not suspected, are thus revealed, and you may better protect yourself.—In dislocation of one side of the jaw the chin is deflected away from the dislocated side. In bilateral dislocation the chin is advanced forward. In the former the face is distorted, while in the latter there is a peculiar expression of fear and distress.—It is sometimes very difficult to remove foreign bodies broken off under the finger-nails. The best way is to apply carefully a ten-per-cent. solution of caustic potash and scrape away the softened portion. This is repeated until the foreign body is exposed.—Seventy-five grains of picric acid dissolved in two ounces of alcohol, to which a quart of water is added, makes an excellent application for burns. There is nothing which deadens the pain better. It should not be used after granulation begins to take place.—After a blow upon the head, the hardened margin of a blood-extravasation is sometimes mistaken for a protruding edge of fractured bone. If in doubt, press gently upon the spot, steadily and continuously. If it is an extravasation it will gradually become pitted by the pressure.—A starch bandage will not set so fast as a plaster one, but except for this it will do everything that may be done with the latter. Wet your bandage slightly before applying it, and then spread the starch paste over every layer. It has the great advantage that the materials for it are found in every house.—If you expect to use a thermo-cautery during an operation, see that your assistant wraps the handle in a sterilized towel before handing it to you.—Don't spend half an hour in carefully sterilizing your hands, and then wipe them on any old towel that is lying around. Work with wet hands if you can't obtain a sterile towel.—An enlarged prostate often projects, as it were, into the bladder, thus increasing the length of the urethral canal. Hence an instrument must often be introduced farther than usual in order to reach the urine.—Look at the foot when a patient complains of enlargement of the femoral lymphatics. A suppurating ingrowing toe-nail or any other septic condition of the toe or foot is probably at fault. If this is properly attended to the glands will soon subside.—Large glands in the neck of adults or old people are very apt to signify that a malignant process is taking place in the neighborhood; hence it is always well to examine the mouth, the tongue, the nose, and the throat carefully in such cases.—In general operative work, it is always useful to have two kinds of artery forceps, pointed and blunt-jawed. The pointed artery forceps are most useful for vessels in and near the skin, as they crush less tissue. The blunt-jawed forceps permits more rapid and efficient hæmostasis in the deeper tissues.—In the treatment of fractures of the long bones, it is practically impossible to bring the broken surfaces end to end in perfect approximation. Our object is simply to accomplish this as nearly as possible, and in the lower limbs to secure such extension as will result in a bone of normal length.—After amputations never wait to apply an artificial limb beyond the time when the stump is well healed and the patient is strong again. Disuse of the stump for too long a time makes it less able to stand the artificial limb. The only exception to this rule is when the operation was done for malignant disease, where early pressure and concussion might favor a return.—In injuries of the skull requiring operation, it is well to remember that the prognosis depends a good deal upon the region involved. Thus in a series of over eight hundred cases it was found that the mortality was one to sixty when the anterior brain was affected, whereas it was one to thirteen in injuries of the central and posterior regions, and one to four and a half in those situated at the base.—*International Journal of Surgery*, September, October, 1899.

## Reviews and Notices.

A Compend of the Practice of Medicine. By Daniel E. Hughes, M.D. Sixth Physician's Edition, thoroughly revised and enlarged. Including a Section on Mental Diseases and a very Complete Section on Skin Diseases. Philadelphia: P. Blakiston's Son & Co. 1899.

The sixth edition of a medical work scarcely calls for any review, for it has already been judged by a host of readers and has been found satisfactory. Certainly that is the case with Dr. Hughes' handy little compend. Originally intended for the use of medical students, its conciseness and completeness soon appealed to the practitioner as well, and the author has consequently added certain subjects, such as insanity, which are not often included in students' manuals. The book is of convenient size and attractively bound in flexible covers.

Traité de Médecine. Publiée sous la direction de MM. Bouchard, Professor à la Faculté de Médecine de Paris, Membre de l'Institut, et Brissaud, Professor à la Faculté de Médecine de Paris, Médecin de l'Hôpital Saint-Antoine. Deuxième édition. Tome III. Paris: Masson et Cie. 1899.

The third volume of the new edition of this great work contains articles on diseases of the skin by Georges Thibierge; venereal diseases, by the same; diseases of the blood, by A. Gilbert; and poisons, by H. Richardière. The first two of these occupy more than two-thirds of the volume, about one hundred pages being devoted to each of the other subjects. Each of these articles is a treatise in itself, and one that is fully up to the times and satisfactory in every respect. The second edition of this work is a true revision and rehandling of the different subjects, and not merely a reprint of the first.

Encyklopaedie der Therapie. Herausgegeben von Oscar Liebreich, Dr. Med., Geheimer Medicinalrath, o.o. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universitat; unter Mitwirkung von Martin Mendelsohn, Dr. Med., Prof., Priv.-Doc. der inneren Medicin an der Friedrich-Wilhelms-Universität, und Arthur Würzburg, Dr. Med., kgl. Sanitätsrath, Bibliothekar im kaiserlichen Gesundheitsamte. Dritter Band, II. Abtheilung. Berlin: August Hirschwald. 1899.

This most useful and practical encyclopedia of treatment is nearing its end, the present part carrying the titles on from Pharyngitis to Secale Cornutum. Some of the most important of the articles are: phlebitis, phlegmon, mushroom poisoning, pneumonia, proteids, ptomains, mercury, management of convalescence, the Roentgen rays, salicylic acid, scarlet fever, serpent venom, sulphur, consumption, scoliosis, and ergot. When this work is completed it will undoubtedly be without a superior among works of the kind in any language.

The Medical Directory of New York, New Jersey, and Connecticut. Edited by E. Eliot Harris, M.D. New York: Trow Directory Printing and Bookbinding Company. 1899.

This new medical directory is gotten out under the auspices of the New York State Medical Association. It contains several lists of physicians as follows: in the Boroughs of Manhattan and the Bronx, of Brooklyn, of Queens, and of Richmond, in New York State outside of the city, in New Jersey, and in Connecticut. The State lists are arranged by cities, towns, and villages, and are supplemented by alphabetical lists. There are also street lists of the physicians in the Boroughs of Brooklyn and of Manhattan and the Bronx. In addition to this the book has lists of dentists and of pharmacists in the three States, the by-laws of the medical societies, and the laws relating to the practice of medicine in New York, New Jersey, and Connecticut. Physicians admitted to the book are regular practitioners only, no mention being made of licensed physicians of other schools. There is an omission which we hope to see supplied in subsequent volumes. The information regarding the hospitals and dispensaries is exceedingly meagre, nothing but the location being recorded. A physician who is sending a patient to a hospital usually knows where the hospital is, but he fre-

quently wants to know the requirements for admission, and also who are the members of the attending staff, as he may wish to refer the patient to one of them. The book is neatly bound in green cloth, and resembles the old "green book," except that it is double the thickness. We welcome this excellent directory, which was so badly needed, and we wish it a very long and useful existence.

THÉRAPEUTIQUE DES MALADIES DU CŒUR ET DE L'AORTE. Par le DOCTEUR ERNEST BARIÉ. Deuxième édition. Paris: Octave Doin, éditeur. Pages 480. 1899.

THIS work is uniform with that of Dr. Auvard, and is one of the same library brought out under the direction of Dujardin-Beaumetz and Terillon. It has the same flexible morocco covers, but is not illustrated. The therapeutics of heart disturbances and diseases have been more carefully considered in the last ten years than ever before. Owing to the prevalence of grippe and the use of the coal-tar products and the increased strain of modern living and working, all physicians find a greater amount of heart troubles to contend with than ever before, and are obliged often to call to their aid every resource conceivable to achieve results for their patients. It is therefore valuable to find in a small compass, ably elucidated and concisely and intelligently stated, as in this book of Monsieur le docteur Barié, heart medication as advocated by the French.

DIAGNOSTIK UND THERAPIE DER DARMKRANKHEITEN. Von DR. I. BOAS. II., Specielle Diagnostik und Therapie der Darmkrankheiten. Leipzig; Verlag von George Thieme. 1899.

THE first part of Boas' work on "Diseases of the Intestine" was favorably reviewed in this journal about two years ago. The present work forms the second part on the same subject, dealing specially with the different diseases of the intestines and their treatment. The writer is one of the best recognized authorities on digestive disorders, and his book on the stomach has won world-wide recognition. As in his first work, Boas here also excels in the practical way in which every subject is discussed. The diction is clear and precise. The work is divided into the following chapters: 1. Acute and Chronic Enteritis. 2. Habitual Constipation. 3. Intestinal Ulcers. 4. Round Ulcer of the Duodenum. 5. Intestinal Neoplasms. 6. Intestinal Obstructions and Occlusions. 7. Appendicitis. 8. Diseases of the Rectum. 9. Nervous Diseases of the Intestines. In the treatment of acute intestinal occlusion or ileus, Boas permits the administration of liquid food in small quantities per os. Lavage of the stomach and high injections of water into the bowel may be tried in appropriate cases. The use of cathartics is deprecated, while opium is highly recommended. Surgical intervention must be given due consideration. We do not hesitate to recommend this work in the highest terms to the medical profession, and to say that it marks great progress in medical literature.

A TEXT-BOOK OF DISEASES OF THE NOSE AND THROAT. By D. BRADEN KYLE, M.D., Clinical Professor of Laryngology and Rhinology, Jefferson Medical College, etc. With 175 illustrations, 23 of them in colors. Philadelphia: W. B. Saunders. 1899.

THE clinical side of this special field of medicine has been fully written up, we might say over-written. There has been a duplication of text-books, many of which have been entirely devoid of original work. It is agreeable to note that there is now a tendency to cultivate more carefully the ground which has already been superficially covered. This latter sentence expresses the feeling which comes to one who reads Dr. Kyle's book. He has deservedly enjoyed a reputation as an expert microscopist, and the volume before us attests his diligence and accuracy as a clinician. Each chapter treating of actual diseases begins with a classification of the affections of the tissues studied. Such a classification is necessarily somewhat of a personal one, but it outlines the task the writer has in mind and makes it easier to follow his lines of reasoning. Many of the illustrations are from his own specimens or have been made from cases immediately under his personal observation. In the matter of treatment, he has purposely gone into details. We especially commend his pathological studies, for on no other foundation can there be erected at the present day a superstructure worth considering. Space does not permit an extended analysis of this work, which is creditable alike to Dr. Kyle and American laryngology. Its clearness of type, vividness of illustrations, and the possession of a model index are all worthy of praise.

## Society Reports.

### NEW YORK ACADEMY OF MEDICINE.

*Anniversary Meeting, November 16, 1899.*

WILLIAM H. THOMSON, M.D., PRESIDENT.

**The Surgery of the Kidney.**—DR. LEWIS S. PILCHER delivered the anniversary discourse, taking the above for his theme. He said that his attention had been first directed to this subject twenty years ago by a case of calculous kidney. This period had been the dawning of a new surgery which had made possible most of the modern surgery of the kidney. In July, 1869, a woman, named Marguerita Kleb, had appealed to Simon, of Heidelberg, for relief from a ureteral fistula left after operation. Many perpexing questions had arisen, and it was not until Simon had nephrectomized thirty dogs that he had been willing to attempt upon a human being so serious an operation. But oh, the blessings that had flowed from this pioneer work! Would any one say that the sacrifice of those thirty dogs was too high a price to pay for the many lives saved and made happy and useful thereby? This same surgeon had, for the first time in the history of surgery, removed a calculous kidney on August 8, 1871, and the patient had done well for twenty-one days, and had given every indication of recovering. But at this time the surgeon had yielded to the custom of that time and had inserted his finger into the wound for the purpose of examining it. A few hours later the woman had had a chill, and this had been followed by general sepsis and death in ten hours. Although this surgeon had never again had an opportunity to extirpate the kidney, the seed sown by him had borne abundant fruit. Touching upon other portions of the field of renal surgery, the speaker said that whether a stone-bearing kidney should be excised or not depended largely upon the state of the kidney tissue itself. When suppuration had already supervened, incision into the organ could be expected to give only temporary relief. The question of the early diagnosis of a renal calculus and the importance of prompt interference could, therefore, hardly be estimated. Likewise in tuberculosis of the kidney it was undeniable that the earlier such a kidney could be removed the better, provided the other kidney was competent to act as an excreting organ. The difficulties attending diagnosis during the earlier period were certainly many, and as both kidneys were often implicated, the results were not commonly very brilliant. An exploratory incision was warranted whenever there were present polyuria, frequent urination, recurrent hæmaturia, and aching loins, even though pus had not appeared in the urine, and no tumefaction could be felt in the region of the kidney. According to the statistics collected by Bangs recently, in about half of the cases operated on a lasting recovery had followed, and in an additional equal proportion of cases great improvement had been effected for the time. In cases of pyonephrosis he favored doing a nephrotomy at first, and later, if nephrectomy seemed absolutely demanded, it should not be undertaken until the surgeon was assured that the other kidney was competent to carry on the work. A very large operative mortality had thus far attended nephrectomy for carcinoma, but

this was largely because the patients had not presented themselves to the surgeon until the disease was far advanced. No more brilliant achievement in surgery had been recorded than the successful efforts of Abbe in removing sarcoma of the kidney. During the past twenty years the conservative surgery of the kidney had been developed as much as had the destructive surgery of this organ. Thus, since 1881 much had been done in the way of fixing movable kidneys. Plastic operations on the pelvis for the relief of valvular obstructions to the inlet of the ureter had been done, but were of still later origin. Methods of diagnosis had improved, surgeons having learned better to interpret the subjective symptoms. Between the years 1890 and 1898 at the Roosevelt Hospital the nephrectomies done there had yielded a mortality of less than nineteen per cent., while of seventeen consecutive nephrectomies done at the Presbyterian Hospital between 1893 and 1896, all the patients had recovered. Chemistry had lent test tubes and reagents, optics its microscopes and reflecting mirrors, bacteriology its plates and incubators, mechanics its cystoscopes, and electricity its light to aid us in the field of renal surgery.

## SECTION ON SURGERY.

*Stated Meeting, November 13, 1899.*

CHARLES N. DOWD, M.D., CHAIRMAN.

**Incision of the Pericardium under Local Anæsthesia.**—DR. H. LILIENTHAL presented a boy of fifteen years who had been admitted to the service of Dr. Morris Manges at the Mount Sinai Hospital on July 6, 1899, with pneumonia of three lobes. The temperature at the time had been 104.5° F., and the pulse rapid. On July 11th the pulse had been 120, the respirations 68, and the temperature 103° F., and pneumococci were found in the sputum. Repeated examinations at that time, and later, failed to show the presence of tubercle bacilli. On July 14th a pericardial murmur had been heard for the first time, and on the 17th the pulse had been irregular, and there had been an increase in the precordial dulness. The pneumonia, however, was resolving. On August 3d streptococci as well as pneumococci had been found in the sputum, but no tubercle bacilli. On August 5th the pericardial friction sounds, which had been absent for a time, had returned, and on the 9th the pulse had reached 132, the respirations had been 32, and the temperature 102° F. On August 13th the pulse had been 142, feeble and irregular. The next day the pericardium had been aspirated and 18.5 ounces of pus removed. Examination at the time had shown numerous pneumococci. On the following day he had been transferred to the surgical side and had come under the speaker's care. At that time there had been some cyanosis, and his condition had been so grave that general anæsthesia had seemed inadvisable. Eucaine beta had been the anæsthetic selected. The boy's face had been screened off and his attention distracted by conversation. About ten minutes before the operation he had received ten minims of Magendie's solution of morphine. One drachm of a six-per-cent. solution of eucaine had been used. An incision over two inches long had then been made from the third to the fifth intercostal space, about half an inch from the sternal border, and another horizontal incision along the fifth interspace. About three-quarters of an inch of the fifth intercostal cartilage had been removed with a scalpel about one-fourth of an inch to the outside of the sternum. The hemorrhage during the operation had been insignificant. The mediastinal tissues, which had become infiltrated and adherent to the pericardium, had then been incised. After passing through about one inch of thickened tissue, under the guidance of an aspirating needle, the pericardium had been opened and the pus had gushed out very freely. The quantity of pus evacuated was enormous, at least forty ounces. Part of the wound had been left open for drainage. About August 22d the pulse had fallen to 110, and at this time daily irrigations with decinormal saline solution had been begun. On September 7th he had been allowed out of bed for the first time, and on the 27th he had been discharged cured. At the present time the pulse was good, and his general condition was most satisfactory. Dr. Lilienthal said that, so far as he had investigated, the case was wholly unique.

**Remarks upon the Surgery of Gall Stones.**—DR. MAURICE H. RICHARDSON, of Boston, presented a paper on this subject, but only read portions of it. He said that a search through his private records had shown one hundred and fifty-three cases of suspected gall stones, eleven of which had been reported prior to 1892. Of these one hundred and fifty-three ninety-five had been operated on. The records of the Massachusetts General Hospital showed that out of a total of seven hundred and twenty-one abdominal operations performed in the year ending June 1, 1899, thirty-four had been for suspected gall stones and fifty-four had been hysterectomies. He mentioned this to give an idea of the comparative frequency of the two operations. Of two hundred and seventy-seven abdominal operations performed in his own service at this hospital during the past twelve months, twenty-one had been for suspected gall stones, with two deaths. Of seventeen deaths from gall stones occurring in his service at the Massachusetts General Hospital since 1892, death had been due to peritonitis in six; to abscess of liver in one, sepsis one, embolism of the pulmonary artery one, œdema of the lungs one; exhaustion without peritonitis, two; shock, two; hemorrhage from the portal vein, one; general capillary oozing and jaundice, one; uræmia, one. It seemed, therefore, that the mortality in operating for gall stones was more influenced by the length of time the condition had existed than by the operative interference. Dr. Richardson said that gall stones might cling very closely to the duct, rendering their removal exceedingly difficult. There had been several cases of spontaneous fracture of the gall stone during its passage downward. The largest stone he had removed had weighed five hundred and forty grains. It should be remembered that the absence of facets did not prove that other stones were not present; he had found as many as ten unfaceted stones in the gall bladder. He had removed one stone large enough to obstruct completely the small intestine, where indeed it had been firmly impacted, and yet the most thorough inquiry into the history had failed to show the slightest evidence of its presence. In one case he had removed three quarts of changed bile in a case of acute cholecystitis. At times the gall bladder would be contracted down so small and hard as to suggest to the examiner the presence of malignant disease. The friability of the wall was important. In acute infections of the gall bladder in some prolonged cases the gall bladder would be so friable that the sutures would be retained with difficulty. He had very frequently observed hemorrhage from the mucous membrane itself after the removal of tension, but, as a rule, it was controlled without much difficulty. The infectiousness of the fluid was indicated more by the constitutional symptoms than by the gross appearances of the fluid. Gall stones might often exist for years without causing much trouble, and then suddenly excite an acute inflammation. The earlier the operative interference the better the chance for recovery. It

was not uncommon to find the gall bladder distended obliquely in the direction of the foramen of Winslow.

Diagnosis: Regarding the diagnosis the speaker said that in typical cases there was rarely any difficulty because of the character of the pain, yet even here it was prudent to search the stools for the passage of stones. The chances of error in diagnosis were slight if the history were reasonably clear. In some instances, although the pain was localized in the epigastrium, operation would show the vermiform appendix alone to be at fault. In connection with the history of intermittent colic the occurrence of pain and jaundice was almost sure to mean gall stones. In many cases a tumor in the region of the gall bladder would be the chief or perhaps the only physical sign. However, the mere presence of a tumor in this region suggested necessarily a great variety of conditions.

Treatment: Surgical relief, Dr. Richardson said, was called for whenever gall stones were believed to be present, for nature was a clumsy operator in such cases. The chief dangers were from shock, hemorrhage, and sepsis. On the side of operative intervention the dangers were trivial and the chances of recovery great, whereas on the other side were many and grave dangers and uncertainties. Even in cases of suspected malignancy exploration was indicated, because one often found only gall stones, and could then give complete relief. The patient should be given the benefit of the doubt. His custom was to make a vertical incision between the fibres of the rectus, at first only large enough to admit of the introduction of the fingers. The gall bladder should be aspirated, for sometimes stones that could not be felt at all before such aspiration could be easily detected after this operation. In most cases considerable hemorrhage occurred from the gall bladder after the introduction of the scoop or even of the finger. It was especially liable to occur if the gall bladder had been overdistended. Having removed from the gall bladder all of the stones, the bladder should be temporarily packed with gauze while a digital exploration of the ducts and of the pancreas was made. To close the normal gall bladder and leave it in the abdominal cavity and close the abdominal wound had been, in his experience, a dangerous proceeding, one causing the surgeon much anxiety. A colleague had reported to him a death occurring after this so-called ideal operation. A number of the surgeons at the Massachusetts General Hospital had a feeling of great distrust regarding immediate closure of the gall bladder, with or without closure of the external wound. One reason for this feeling was the tendency after suturing for hemorrhage to take place from the inverted edges of the mucous membrane, and by distending the gall bladder so to stretch the sutures as to allow of leakage of bile. In some instances he had closed the gall bladder and fastened it to the wound in such a manner that if bile should escape it would come out through the external wound. So far as he knew, there had been no trouble from the insertion of gauze to guard against such accidents.

Biliary Fistula: In one or two instances biliary fistulæ had persisted. If bile escaped from the sinus and none was found in the stools it was clear that there was an obstruction of the common duct. Such a condition after an operation for gall stones, if associated with jaundice, pointed strongly to a stone left behind in the common duct. In one case of persistent biliary fistula the patient had been well so long as the bile had escaped, but as soon as the flow of bile had been obstructed she had become ill. She had not desired an operation, so she had been fed on ox gall and the bile allowed to escape. In cases of this kind in which the presence of a stone was doubtful this treatment seemed quite proper. Contamination of the operative field in ordinary operations on the gall bladder seemed to him not very likely to occur; it was quite different from operations on the appendix. In infections of the gall bladder the operation could be done without much danger of infecting the abdomen, no matter how bad the local infection might be.

Stones in the Ducts: When stones were impacted in the cystic duct they might be squeezed up into the gall bladder with the thumb and finger. Sometimes the stone would be so intimately adherent to the altered mucous membrane as to necessitate cutting down upon it and removing it piecemeal. He was not sure that it would not be well to remove the gall bladder in all cases in which it was necessary to incise a duct. In some instances the gall bladder would be apparently malignant. A thickened, adherent gall bladder containing stones should be removed, whether malignant or not. When the symptoms indicated obstruction in the common duct it was necessary to make a long incision. He had not found it necessary to cut across the rectus above, or deviate from the straight line below, as had been suggested. Digital exploration for malignant disease was sometimes misleading and unsatisfactory. When incision into the duct was made, great care should be taken that the large veins were not in the way. All incisions made around the foramen of Winslow should be made with the greatest intelligence and caution. While no doubt the hemorrhage could be checked by ligation of the portal vein, the patient would die as a result of this ligation. By means of fine sutures a rent in the vein could be satisfactorily closed.

Hemorrhage: He had always been taught that it was dangerous to operate in cases of jaundice, yet he had learned to operate with great confidence in such cases, and had done so successfully for ten years. He had then operated upon what had appeared to be an exceptionally favorable case in every respect, yet the patient had died within twelve hours from a most extensive capillary hemorrhage. It was prudent to tie all points showing any tendency to bleed.

Dr. Robert F. Weir said that he agreed with the reader of the paper that in cases of gall stones affecting the gall bladder, after incising the gall bladder and removing the stone it was well to stitch the bladder to the external wound and leave the latter open. It was sometimes well to drain the gall bladder by the introduction of a tube. With the gall bladder left open there would not only be an exit for the escape of bile, but an opportunity would be afforded for overcoming a subsequent obstruction. Lately he had adopted the plan of throwing a quantity of water into the bladder and suturing it. He had only once used the injection of air for this purpose, or for the detection of the point of resistance or obstruction in the common duct. Cases of obstruction of the common duct were of two classes, those presenting few adhesions, and those having many adhesions. In the former class, with the finger in the foramen of Winslow the surgeon could command the gall passages fairly satisfactorily. With obstructions in the upper portion of the duct there was likely to be hemorrhage. It was also in the lower half that risk from the near presence of normal or aberrant vessels was the greatest. He had found it difficult by the ordinary method to close up the opening in the duct after the extraction of the stone. Finding that failure to close the duct in such cases did no harm provided a free escape for the bile was secured, he had more recently adopted the practice of not attempting to close up the opening in the duct. So far this practice had proved entirely satisfactory. For cases of obstruction of the ducts or of extensive adhesions, he favored the more extensive opening known as the "Bevan incision."

**Prevention of Gall-Bladder Fistula.**—Dr. Charles McBurney said that he had been very much impressed with the reports of some surgeons, because of the extraordinary freedom from mortality which they had secured in operating upon these exceedingly difficult cases. Such results were probably best explained by supposing that there had been a most careful selection of favorable cases made. He thought there could be no doubt that quite a large number of cases of gall stones experienced no harm from the presence of the stones; the difficulty was to determine what cases were of this class. That this was so was proved by the frequent discovery of gall stones at autopsies in cases giving no history pointing to such a condition. He felt, therefore, inclined to leave certain of these patients entirely alone, particularly the elderly ones, or those very fat persons in whom the symptoms had been quite slight. With these exceptions he believed thoroughly that the earlier the operation was undertaken the better the results. It was far better to operate upon gall stones in the bladder before the supervention of jaundice, because of the increased likelihood of hemorrhage during operation. He had seen a number of cases of annoying biliary fistula following incision into the gall bladder. Dr. William Jones, of Rising City, Neb., had made some interesting experiments with a view of preventing the long continuance of fistula after operations on the gall bladder. These experiments had been made upon dogs with great success. Dr. McBurney said that he had tried the method on the human subject, and with perfect success. The method was applicable only to cases in which the gall bladder was still fairly flexible. The method was to invert the orifice made by the surgeon's knife so that on closure of the wound this orifice was inverted and the peritoneal coats were brought in contact. Through this inverted orifice the drainage tube was inserted for the short period required. When treated in this way the fistula would close within forty-eight hours after the removal of the tube. The speaker said that after the great dangers depicted by Dr. Richardson as attendant upon incision of the common duct, he could not see why such a method should be practised when it was so easy and so comparatively safe to go into the duodenum and remove the stone from below. He had done this operation six times without the slightest difficulty from closure of the wound. One patient had died of persistent vomiting of obscure nature, but apparently due to complete intestinal paresis.

**Hemorrhage and Jaundice.**—Dr. B. Farquhar Curtis said that he had operated upon a very stout elderly woman with a history of impacted gall stones in the common duct, dating back for some months. The symptoms had been very ill defined. The operation had proved to be difficult because of her obesity. The stone had been removed from the duct, but it had been impossible to close the opening. About one week after the operation marked oozing had begun from the granulations in the wound. This hemorrhage had been kept in check as far as possible by packing, and about ten days after the operation he had ventured to plug the wound tightly so as to prevent the escape of bile. After a few hours the bile had escaped into the bowel. The hemorrhage from the granulations had continued at each dressing for two or three weeks afterward. The patient had recovered and the wound had closed, but she had gone on to the later stages of cirrhosis, which had been distinct at the time of the operation. It had occurred to him that possibly the hemorrhage had resulted from cirrhotic obstruction. The mere presence of jaundice did not seem to account for the hemorrhage, because of the few cases of this kind in comparison with the many operations on those suffering from jaundice.

Dr. Robert Abbe said that he had twice seen enormous masses of hypertrophy of the gall bladder in long-standing cases. In one of these there had been a mass double the size of the fist presenting all the appearance of malignancy, but the patient had subsequently recovered, and a secondary laparotomy had proved its non-malignancy. He had had considerable experience with the removal of stones from the common duct and suturing of the opening. Such stones were quite commonly strictured on both sides. In several cases he had left the wound in the duct open, and it had closed subsequently without any untoward result.

Dr. Robert T. Morris suggested that in the case in which non-faceted stones had been found there might have been adhesions in the gall bladder limiting the mobility of the latter.

Dr. J. B. Murphy, of Chicago, said that in cases in which there was jaundice he did the least possible operating. If the stone had existed in the common duct for a long time, he did a cholecystotomy and cured the patient of jaundice, and then he felt that he could go down with safety and remove the stone. He had had a very sad experience with hemorrhage, and was greatly afraid of it in this class of cases. He had been particularly pleased at the candor with which the reader of the paper had detailed his failures.

Dr. Richardson said that he too would object most strongly to operating upon elderly people except when there was much urgency. The wounds in the duct should be allowed to close just as wounds in the urethra. While he thought very highly of Dr. McBurney's operation for approaching the stone from the duodenum, he had had only one case in which the stone had been in the lower portion, and hence he could not speak regarding this operation from personal experience.

## NEW YORK STATE ASSOCIATION OF RAILWAY SURGEONS.

*Proceedings of the Ninth Annual Meeting, Held at the New York Academy of Medicine, November 16, 1899.*

The association was called to order by the president, Dr. Theodore D. Mills, of Middletown, N. Y.

"The Physical Fitness of Railway Employees" was the special topic for consideration during the morning session.

**As Viewed from the Operating Department.**—R. R. Richards, Esq., of Chicago, Ill., general claim agent of the Chicago and Northwestern Railroad, read a paper with this title. The last report of the Interstate Commerce Commission told us that there were 189,396 miles of railroad in this country, and that 874,558 men were employed in the operation and maintenance of the same; that last year 489,444,189 passengers were carried and 741,705,946 tons of freight moved; that during the year 1898 there were 1,958 employees killed; 31,761 injured; 221 passengers killed, and 2,945 injured; 4,680 other persons killed and 6,176 injured, making a total of 6,859 killed and 48,882 injured. This frightful loss of life, together with the great loss to property, suggested that some standard of efficiency should be demanded from the employees. If a system of examination and the adoption of an age limit were established, the following benefits would be secured: 1. The company would secure the services of men who were physically capable of performing their duties properly, and who would in all probability be able to do so for many years. 2. Men who were physically unfit for the work would be kept out of the service, and the risk that their employment would necessarily entail would be

avoided; and at the same time the company would be protected from fraudulent claims for injury which this examination would detect. 3. The number of accidents and resulting expense would be reduced. 3. By reducing the number of accidents and making the business less dangerous a higher class of men would be encouraged to enter the service. 5. In case of injury it was well known that a sound man would get well quicker and make a better recovery than an infirm or diseased one, thereby reducing the expense of adjusting his claim, as well as the cost of caring for him.

**As Viewed from the Surgical Department.**—Dr. G. P. Conn, of Concord, N. H., chief surgeon of the Boston and Montreal Railroad, read this paper. He said that physical fitness, good discipline, and an intelligent understanding of the duties to be performed were as necessary in the case of railroad employees as in the army, navy, or civil service. Dr. Conn assumed and demonstrated—first, that it was desirable to have only good, sound men as employees; second, that in having due regard to physical fitness, many men that were mentally incompetent and constitutionally unsound would be rejected; third, that the establishment of such a service would, in the long run, be a source of profit rather than of loss to a railroad company.

**As Viewed by the Oculist and Aurist.**—Dr. Joseph White, of Richmond, Va., ophthalmic surgeon to the Chesapeake and Ohio Railroad, read this paper. The following conclusions were drawn from his remarks: 1. That perfect color perception (not color knowledge) for red and green, vision of $\frac{20}{20}$ without glasses, and with hyperopia over 2 D barred, normal visual fields, and good hearing should be requisite to prove the physical fitness of all applicants for any position in railway service in which they may be connected with the signal service of running trains, or who may be in the line of promotion to such positions. 2. That they should be re-examined when they were promoted to engineman, conductor, etc., and the same standard should be required. 3. That a re-examination should also be made after injury or illness of any kind that might cause depreciation of the color sense, sight, or hearing. 4. That, if addicted to the constant use of liquor or tobacco, they should be examined at stated intervals, such intervals to be fixed by the results of experience. 5. If in these re-examinations the color sense should be found to be impaired, or the vision lower than $\frac{20}{40}$, or hearing less than two-thirds of normal, they should be relieved of duty in running trains or transferred to some other position. 6. That employees not directly engaged in running trains, such as telegraph operators, station agents, baggage men, etc., should have normal color sense, but that a vision of $\frac{20}{40}$ or hearing less than two-thirds of normal, will do. 7. That these examinations should be conducted by a surgeon of the road, or by some responsible employee who had been thoroughly instructed in the methods of making them, and whose own color sense, vision, and hearing should be up to the highest standard, and who should refer all cases about which there was the slightest doubt to an ophthalmic and aural surgeon in the employ of the road. 8. That all railroads should adopt these or similar regulations for testing the physical fitness of their employees, both for their own interests and those of their patrons. 9. That whenever and wherever practicable legislation should be encouraged to bring about a general acceptance of the much-needed reform.

**The Medico-Legal Features of Physical Fitness.**—L. L. Gilbert, Esq., of Pittsburg, Pa., read this paper. He said that if, by physical examination and record, some of the uncertainties which beset the attorney and adjuster of claims could be removed, it would be comparatively easy to determine what should be done by way of compensation for an injury. With a proper and thorough physical examination, and the employment of the sound and healthy only, the possibility of fraud would be greatly reduced, the service be bettered, and the corporation could perform more satisfactorily the duties for which it was created. The medico-legal features of the subject were, in a great measure, negative in their character; if the physical features were removed, the legal will to a great extent disappear. One factor must, however, be noted: the employer was responsible for an accident caused by defect in material or construction. Now the question might justly be asked: What was the difference whether the cause contributing to the injury of a third party was an imperfect tool or an imperfect man, provided the imperfect physical condition had caused the injury to the third person? Mr. Gilbert did not think that men already in the employ of a company should be discharged for causes which would prevent new men from entering. He confessed himself unable to cope with this question, or to determine what the new standard should be.

The subject was discussed by Clark Bell, Esq., of New York; Dr. J. F. Valentine, of Richmond Hill, L. I., chief surgeon of the Long Island Railroad, and George Marsden, claim agent of the New York, Ontario, and Western Railway.

**President's Address: The Railway Surgeon, His Relation to the Railway Companies.**—Dr. Theodore D. Mills, the president, made the following address: That a competent corps of experienced surgeons was needed in connection with the operation of every large railroad, was a fact patent to every one. The railway companies were quick to appreciate this fact, as was shown by the large number of companies which had a systematic surgical service. The regular surgeon of a company felt a sense of responsibility, and responded with more readiness to calls, than a chance surgeon, and his large experience with this kind of injuries made him more efficient than the surgeon who handled only a few cases. The statement that "corporations have no souls" was false. As a rule railway companies were just in befriending those who had been injured, and in many cases had given a substantial gratuity when employees had retired from the service. When we consider the way in which railway companies were imposed upon by designing lawyers, who too often found willing coadjutors in the medical profession, we could not wonder that they would not pay out money unless forced to do so. The railway surgeon was of service to the company, in these claims for personal injuries, by giving full information as to the exact nature of the injuries and the effect they were liable to leave on the person injured. When placed upon the witness-stand the surgeon of the company would state facts with impartiality and endeavor to make the case clearly understood by the average juror. The railway surgeons through their associations should co-operate with the managers and employers in reducing the number of accidents occurring each year on the different roads of the country. The occupation of railroading had become safer than it formerly was, and it followed from this that the class of men applying for these positions must have improved in like proportion. The subject under discussion might well have included mental and moral fitness as well as physical. The railroad surgeon owed a duty to the travelling public in protecting them from disease as well as injury. The association should discuss the most thorough and efficient means of disinfection of the passenger and sleeping coaches. It was a fact that there was probably greater danger of contracting contagious diseases while in transit by rail than in many other places. The repeated draught of

air through the coaches widely disseminated the infection, and the reason so many escaped was because they were immune, from having had the disease early in life. The meetings of the association were calculated to stimulate its members to render better service to the roads which they represented, and whatever was recommended as of practical value in the care of the injured or in safeguarding the travelling public would be appreciated and acted upon by railway managers.

Other papers read were: "Where Hydrogen Dioxide is Harmful," by Dr. Robert T. Morris; "Dislocation of the Shoulder, with Fracture of the Neck of the Humerus" (three cases treated by operation), by Dr. B. F. Curtis; and "Emergent Surgery," by Dr. John Eddy.

The following officers were elected for the ensuing year: *President*, John L. Eddy, of Olean, N. Y.; *Vice-Presidents*, W. R. Townsend, of New York; H. P. Jach, of Canisteo, N. Y.; *Secretary*, C. B. Herrick, of Troy, N. Y.; *Treasurer*, Theodore D. Mills, of Middletown, N. Y.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

RADSHAW LECTURE ON CARDIAC MURMURS—SOCIETIES, OPHTHALMOLOGICAL, CLINICAL, GYNÆCOLOGICAL, BALNEOLOGICAL—OÖPHORECTOMY, AFTER-EFFECTS—ACCOMMODATION FOR LUNATICS—MATRON AND SURGEON—SURGEONS FOR AFRICA.

London, November 3, 1899.

Yesterday Dr. A. Foxwell delivered the Bradshaw lecture at the Royal College of Physicians, taking as his subject "The Causation of Functional Heart Murmurs." Dr. Foxwell has for years devoted attention to this obscure subject, and has now arrived at definite conclusions. As he would not in one lecture deal with all such murmurs, he took up the commonest and most obscure, that heard over the second and third left spaces, systolic, never accompanied by a diastolic element, and which he called the pulmonary murmur. Excluding by arguments and cases other causes, he came to the conclusion that this murmur is due to dilatation of the conus arteriosus and pulmonary artery, with carrying up of the root of the artery, so that in the supine position it tends to lie directly over the bifurcation. This abnormality Dr. Foxwell has constantly found in patients who died with this functional murmur, and he gave a good deal of circumstantial evidence in support of his opinion. To this he added experiments to show that the murmur can be heard after death in a heart over which it was present during life; that it cannot be heard after death in a healthy heart; and that it can be produced in such healthy heart by locally dilating the conus and pulmonary artery. To prove these statements, twenty-one experiments he had carried out were described. The lecturer also quoted with various degrees of fulness thirty-one cases, so that from a clinical as well as an experimental standpoint his views demand the attention of teachers and text-book writers as well as practitioners.

Mr. Anderson Critchett, the new president of the Ophthalmological Society, gave an address at the opening meeting of the session in which he paid a tribute to his predecessors. He also expressed the regret he felt that his honored father had not lived to occupy the chair. That feeling is natural to the members of the society, but George Critchett's fame is world-wide, and to those who knew him his memory is dear as a man, while as one of the great pioneers of ophthalmology his name is deeply engraved on the history of the specialty. That specialty is well to the fore now—Anderson Critchett president of one society, and his colleague, Mr. Juler, of another, the Harveian.

There was an interesting exhibition of cases at the Clinical Society on Friday evening. Mr. Turner had a case of actinomycosis in process of cure. A supposed abscess in the neck had been opened. A fistula discharging a thin, purulent fluid was left. On admission to hospital this was examined and the ray fungus found. Iodide of potassium was given and the cavity scraped with satisfactory result. Mr. Slater observed that the fungus was not readily found in man, and questioned whether the disease was caused, as supposed, by the fungus. It might be due to more than one organism. Mr. Barker suggested that the fungus entered by the alimentary canal, as the disease usually occurred in some connection with this.

Mr. Turner also showed a case as osteitis deformans. There was swelling of the upper jaw of eight weeks' duration, and some also of the head. The tibiæ and ribs were also affected. The patient improved under iodide, but there was loss of weight, and it was admitted that the case might turn out to be one of malignant disease.

Dr. Herringham showed a man, aged thirty years, with symptoms of chronic rheumatism, followed by "deadness" of the hands coming on at times. Raynaud described local syncope, but in this case the skin seemed to be the seat of the appearance, and it was observed in other parts, such as the back. The radial pulse was normal. The wrist flexors were contracted, and the tendons grated in the sheaths on movement. The attacks had subsided since the man had been kept in bed.

Mr. Eve showed a woman, aged forty-four years, with recurrent cancer of the breast. She came to him in 1895 with ulcerated scirrhus. He removed the breast and cleared out the axilla. In 1898 nodules appeared above the scar with infiltration at its centre, and the supraclavicular glands were enlarged. He removed the ovaries and gave thyroid extract, gr. xv.–xx. daily. In three months the infiltration and glandular enlargement had disappeared. In March last she seemed free from disease, but nodules have since formed round the scar, and the glands in the posterior triangle have enlarged. It seemed as if the disease had been delayed or rendered latent for a time.

Mr. Boyd said that oöphorectomy had a marked effect in some cases, and none at all in others. It was impossible to say in advance which cases would benefit. Some of the most unlikely-looking cases had given good results.

Mr. Watson Cheyne mentioned cases he had had this year. One improved for six months and then rapidly went back; in another case the breast was removed six years ago; five years afterward another operation was performed for recurrence; six months later glands deep down in the neck enlarged. Oöphorectomy was done in July, and when the patient was seen the other day the disease seemed to have quite disappeared. In a third case the patient had undergone several operations and came to him first in May with a large inoperable mass. She had also a large fibroid and was losing much blood. He therefore felt justified in removing the ovaries and at the same time as much as possible of the cancerous mass. That was six months ago, and the fibroid has disappeared and the cancer has not yet recurred. He agreed that it is impossible to say beforehand whether a case will benefit by oöphorectomy.

In connection with the foregoing discussion another question just raised at a sister society, the Gynæcological, may be considered. This is the after-effects of

removal of the appendages, which was brought forward by Mr. Furneaux Jordan in a paper embodying statistics of all the cases in which he had performed this operation, as well as those in which he had removed the uterus. The tables include thirty-eight cases of the former and twenty-four of the latter. Of these, various particulars are classified bearing more or less closely on the point, Mr. Jordan's main object being to determine whether patients suffered more after one operation than the other. His own conclusion was that it is not simply a question as to which organs are removed, but as to the age of the patient; the nearer to the time of the natural menopause the less being the disturbance. He found post-operative troubles less after oöphorectomy for myoma than after removal of diseased appendages, but then patients of the latter class are generally older.

Other questions naturally arose from Mr. Jordan's tables, and were duly discussed, but on the point here considered the speakers mostly agreed with his views.

The president, Dr. Macnaughton-Jones, in the course of his remarks expressed surprise that the teachings of Battey, Tait, and many of the American school had been overlooked, and said it was a growing opinion both here and in America that the uterus had often been removed when it would have been better to have left it alone.

At the Balneological and Climatological Association the announcement was made that the editor of the *Journal*, Dr. Hyde, of Buxton, was dangerously ill, and a vote of sympathy was unanimously passed. The October number of the *Journal*, just out, contains a note by the secretaries of the association, dated October 14th, expressing their sympathy on his critical condition. I have just heard that he is somewhat better.

The alleged great increase in lunacy has been a good deal discussed. The enormous and rapid growth in the cost of providing accommodation is continually being brought home to rate payers. Here is another example. The Surrey County Council has just purchased Netherne House estate for £10,000, so as to provide further accommodation for eight hundred or one thousand asylum patients. Some of us will soon be inquiring whether it is not possible to diminish the cost of asylums by utilizing the work of some of the patients—a plan, I understand, that is on trial on your side of the Atlantic.

It is an ancient proverb that a woman is at the bottom of every piece of mischief. In hospital management the proverb is apt to be verified. The matron, or lady superintendent, or chief of the nursing staff, however designated, is too often insensible to the duty of yielding to discipline, though ready enough to enforce it with the utmost rigor against her subordinates. There has been trouble of this sort at Lowestoft, where the committee of the hospital, after investigation, found that charges brought by the matron against one of the surgeons were not proved, but that two out of six charges against the matron were proved; one of them being the use of insulting language about one of the staff, requiring an apology. When will committees learn that discipline must be enforced even against women? Such a breach should have entailed dismissal.

Mr. Makins and Mr. Treves are going to South Africa. Mr. Makins is to set sail to-morrow with Sir W. MacCormac, and Mr. Treves to-morrow week. These civil surgeons are to be paid for their patriotism at the rate of £5,000 a year and allowances. There are army surgeons both on the active list and retired who would be delighted to go on such terms, and whose experience is greater than that of their civil confrères.

---

**Puerperal Endometritis.**—Injection of alcohol in a fifty-per-cent. solution into the uterus.—AHLFELD.

## COMPARATIVE CHEST MEASUREMENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In looking over some back numbers of the MEDICAL RECORD, I find in the issue of July 29, 1899, some statements from the pen of Dr. H. M. Lee, under the heading of "Comparative Chest Measurements," which are so far from what my experience seems to have taught, that I cannot but believe it contains some typographical errors.

Dr. Lee gives us the results of chest measurements of eight hundred men between the ages of eighteen and fifty years—the average age being twenty-six. These eight hundred men were all passed for enlistment in the army by the board of examining surgeons. The "majority were accustomed to heavy exercise in their daily work, many being much in the open air, all well built and muscular."

Their average chest measurement at full expiration was $29\frac{2}{5}$ inches (about 746 mm.), and full inspiration he gives at $33\frac{1}{5}$ inches (about 844 mm.)

College students as a class are not such physically favored men as are those whose measurements have been quoted. Their average age would be probably between eighteen and nineteen years (actual average not made). They, like the enlisted men, come from all classes of society, but are far from all being "well built and muscular"—a majority of them having been engaged in no occupation which would tend toward good physical development, but in many cases exactly the reverse. Unfortunately the figures at my command do not give the average chest at full expiration, but only that at repose, that is, the measurements were taken while the subject was quietly talking. The averages of these measures, taken from several thousand students, give for chest at repose 887 mm., and chest expanded 924 mm., or about $34\frac{2}{5}$ and $36\frac{2}{5}$ inches respectively. Or, stated in another way, the chest in repose of these students in five inches larger than the collapsed measure of the soldiers, while the expanded chest of the former is $3\frac{1}{5}$ inches greater than that of the enlisted men.

Of course it is understood that the tape in all cases was passed next the skin, but unless the measures for the two classes of men were made at very different anatomical points (that in the case of the students alway being across the nipples) it would seem necessary, in order to account for the great differences in the records of the two observations, to think the types were at fault.

E. HITCHCOCK, JR., M.D.

ITHACA, N. Y., November 9, 1899.

---

## OPIUM TREATMENT IN APPENDICITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In to-day's RECORD under the caption, "Opium Treatment in Appendicitis," Dr. Morris makes some very positive remarks which seem to me, a general practitioner, unjust in their ethical aspect and incorrect from a practical view-point. Dr. Morris is dealing with an abstraction for which there is a positive remedy. What this remedy is in Dr. Morris' hand we all know. But all of us do not meet with acute appendicitis as Dr. Morris sees it. Some cases are so mild that they get better with bed rest and dieting. Others demand opium; and still others cannot get well unless the surgeon's knife and technique help them to do so. All grave cases are not severe, nor are all acutely severe cases grave in their course, or after the attack is over. It is not rational to make diseases fit our remedies. When we do so we are taking huge liberties and much for granted. Cases differ, and consequently they demand different methods or plans of treatment. There is no one best way of treating ap-

pendicitis, because there is no one uniform entity to treat.

Of course, if appendicitis were a disease of uniform phenomena evolved from a certain set of conditions always the same, there would be only one uniform method of treatment, and, if all this were so, then, if practitioners did not practise the established uniform rule they would abuse the trust of their patients—ay, as Dr. Morris puts it, violate those trusts. But, judging as matters are met with individually and in the concrete, I must say that Dr. Morris' dictum is a slur. Furthermore, every practitioner must judge in these matters, not by the expressed tastes and teachings of this or that surgeon, this or that physician, but by the facts as they present themselves. Statistics avail nothing in individual cases. They are not diagnostic guides. Statistics simply illuminate the impressions that have been developed by observation, good or bad, or both. When the general practitioner tries to defend his practice, he has one great disadvantage to contend against, and that is his inability to produce a great array of statistics. But it should not be overlooked that statistics from hospitals and other sources are verified or negatived by his cases, and his cases are verities. All statistics are to him only compendious abstractions of added individual cases. No sensible general practitioner bases his impressions on his own personal observations, although he attaches a good deal of importance to them. His impressions are largely nourished and shaped by what he reads and what he sees. And not the least important and instructive data have never been found in print—his own mistakes and the mistakes of others, his consultants and teachers.

Dr. Morris' letter is brimful of sincerity and energy, but his contentions lack a due sense of justice, and his language is violent. Neither he nor men who think and do as Dr. Rochester does and thinks "violate the trust of numerous patients." Dr. Morris is dealing with abstractions, and his conclusions cannot be made to square with all the facts. Nothing facilitates the settlement of empirical questions so easily as abstract means. The diagnosis and treatment of appendicitis are altogether empirical matters. Therefore, let's be practical and diffident.

ADOLPH RUPP, M.D.

426 WEST THIRTY-FOURTH STREET,
NOVEMBER 18, 1899.

## Therapeutic Hints.

**Pruritus.**—

℞ Methyl salicylat ..... 2 gm.
Zinci oxidi,
Vaselini.....āā 20 "
M. ft. ung.

—LEREDDE.

**Enteroptosis.**—The indications for the treatment of enteroptosis, as originally recommended by Glénard, are as follows: (1) The intestines must be elevated and kept in their new position. (2) The abdominal pressure must be increased. (3) The bowels must be regulated. (4) The secretions of the intestinal glands must be increased. (5) The digestion and nutrition must be regulated and stimulated. (6) The whole organism must be strengthened. These indications, in many instances, are met by the body binder so applied as to exert upward pressure and thus support the prolapsed organs while it increases the intra-abdominal pressure. It may be made by ordinary gray cotton pinned firmly about the body.—W. F. HAMILTON, *The Montreal Medical Journal*, September.

**Chronic Laryngeal Phthisis.** — As a calming measure:

℞ Cocain. hydrochl ..... 2 gm.
Morphin. hydrochl..... 1 "
Antipyrin..... 1 "
Glycerin. neutr..... 60 "
M. S. A teaspoonful in half a glass of distilled water as a gargle or spray before meals.

As a general measure if eating becomes impossible because of pain:

℞ Beechwood creosote ..... 2 gm.
Salol ..... 2 "
Iodoform ..... 0.05 cgm.
Olive oil..... 200 "

To be used as a rectal injection; also nourishing enemata with eggs, milk, rum, or peptone in bouillon.—CASTEX, *Gaz. des Hôpitaux*, September 21st.

**Asthma.**—

℞ Heroin. hydrochlor..... 0.1
Aquæ amygd. amar ..... 20.0
M. S. Fifteen to twenty drops t.i.d.

Or:

℞ Heroin ..... 0.15
Extr. gentian ..... 2.0
Pulv. glycyrrh.. ..... q.s.
Ft. pil. No. xxx. S. One pill t.i.d.

—FLORET.

**Epistaxis.**—

℞ Antipyrin ..... 0.5
Tannin..... 1.0
Sacch. alb ..... 10.0
M. S. Apply as snuff.

—RENDU.

**Coryza.**—

℞ Extr. hyoscyami ..... 0.2
Potassii iodidi,
Potassii bicarb.....āā 2.0
Extr. glycyrrhiz ..... 5.0
Aquæ..... 120.0
M. S. Tablespoonful every hour.

—*Riforma Medica.*

**Ozæna.**—

℞ Creosote..... 5
Alcohol (seventy per cent.)..... 10
Glycerin..... 40
M. S. Apply locally.

—FERRARI.

**Tetanus.**—Every two hours fifteen minims of a two-per-cent. carbolic solution should be injected. One case showed rapid improvement after about three drachms of the solution had been injected.—*Il Policlinico.*

**A Palatable Quinine Mixture for Children.**—Greanellé (*New York Medical Journal*, October 28, 1899, p. 628) recommends the following mixture as a tonic and malarial prophylactic for children living in malarious sections:

1.

℞ Quinine hydrochlorat..... gr. v.–x.
Alcohol..... ʒ i.
M.

2.

℞ Oil of cinnamon,
Oil of anise.....āā ♏ xxx.–xl.
Magnesia..... sufficient quantity.
Water..... ʒ i.
M. To stand for some hours and be filtered.

Mix 1 and 2 and add

3.

℞ Simple syrup..... ʒ iij.
Solution of carmine or cochineal..... gtt. v.
Dose: ʒ i. or ʒ ii. as directed.

Saccharin is small quantity helps to disguise the larger dose of quinine. Small doses of Fowler's solution may be added if indicated, or sodium bromide for children made irritable by quinine.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 18, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 125 | 151 |
| Typhoid fever | 67 | 22 |
| Scarlet fever | 130 | 10 |
| Measles | 248 | 12 |
| Diphtheria | 274 | 46 |
| Laryngeal diphtheria (croup) | 15 | 9 |
| Cerebro-spinal meningitis | 0 | 2 |
| Chicken-pox | 19 | 0 |

**Zacharin on Venesection.**—Zacharin, the great Russian doctor, was a firm believer in the good effected by venesection in certain classes of maladies, and he deplored the total desuetude into which the practice has fallen. Speaking of blood-letting in Russia he said: "As regards medical practice with us, with the exception of Moscow and the physicians who are the followers of Moscow methods in medicine, everywhere else in the principal medical centres, the university cities, as well as in the regions embraced by their influence, blood-letting and abstraction of blood in general are looked upon, as far as I know, with disfavor. I am unable to bring before you any literary material on the subject, as I am not aware of the existence of any such; but as far as is known from practice, the stand taken against blood-letting is of a pronouncedly negative nature, at least in the above-named localities. . . . Turning now to Moscow and the region influenced by its teachings I will first of all touch upon my personal relation to the subject under discussion. During my student years and my clinical service blood-letting was practised frequently and unsparingly, so that I had many an opportunity to witness its undoubted value when it could not be replaced in many cases; while in others I also saw great harm caused by it. Of course only later on, as my practical experience began to mature, did I learn to appreciate with greater exactness its beneficial as well as its harmful effects. The errors of the medical practice of those times consisted in this, that it was taught that blood-letting would cure diseases—inflammations, considering as an inflammation pneumonia, acute articular rheumatism, etc.; consequently, without taking into account the condition of the patient's strength, they resorted not only to one but to repeated blood-lettings, not curing the disease but debilitating the patient, thus increasing to a fatal extent the conditions favoring a bad termination of the disease." Dr. Zacharin recommended venesection in certain disturbances of the cerebral circulation, in the presence of evident symptoms of threatening or already occurring cerebral apoplexy in patients with a chronic nephritis and hypertrophy of the left ventricle, and in some disturbances of the circulation within the chest. He advised local blood-letting in acute pleuro-pneumonia and acute pleurisy and in various other conditions in which the taking away of blood would relieve without undue weakening.

**Heredity in Cancer.**—The fact that several members in successive generations of a given family have died of cancer is commonly accepted as proof that the disease is hereditary. This is far from being the case. Cancer causes a certain average number of deaths among a given number of persons. The death rate from cancer is insignificant until the age of thirty-five years is reached, rapidly increasing at each higher age period. On the basis of the national figures for Great Britain for 1887–89, one out of twenty-one men and one out of twelve women die eventually of cancerous disease. Mr. G. King, F.I.A., makes the following remarks upon this important point: Given a certain probability of death from cancer, and knowing the number of a family, it is easy to calculate the probability of one, two, or more of them dying of cancer quite independently of heredity. Even if heredity was proved to be absolutely inoperative, it is certain that there would be families among whom numerous deaths from cancer would occur. It does not prove heredity to show that in one family five deaths, say, occurred from cancer. This might happen from mere chance, and in fact such cases must occur without heredity at all. De Morgan worked out the probability of one thousand successive heads being thrown in tossing a coin, and he showed that given a sufficient number of people starting to toss coins it was a certainty that at least one of them would toss one thousand consecutive heads. So, given a sufficient number of families, it is a certainty, even if there be no such thing as heredity, that of at least one family say ten members will die of cancer. The only absolute proof of heredity would be to show that cancer occurred frequently in certain families and practically nowhere else; short of this, the probability of heredity of cancer would be increased if it could be shown that cancer was much more common in certain families than in the average of the whole community, due allowance being made for variations in age and sex distribution.—Newsholme's "Vital Statistics."

**Poisoning by Means of Clothing in the Eighteenth Century.**—The poisoned shirt, says one of the witnesses, herself an "accusée," presented no extraordinary appearance. It was slightly rumpled and looked as though badly laundered, possibly a little stiffer than ordinary. When she showed it to her accomplice she told him that nothing had been done to the body of the shirt; that only the tail had been prepared and that the effect would be no more than to cause an eruption or inflammation with great pains and dolors behind and to the neighboring parts of M. Poulaillon, the intended victim, and when he was examined nothing extraordinary would be found. The eruption was diagnosed as that of syphilis, and mercury was prescribed. It or some other thing was given, and M. Poulaillon died. How was this famous shirt prepared? Soaking it in an arsenical solution would not suffice, and we surmise that it was well rubbed with an arsenical soap similar to that used by naturalists to-day for preserving the skin of birds and animals. This vehicle affords the only means of concentrating sufficient poison in the tissue of the linen to produce the effect related.—*Scientific American.*

**Quinine Plantations.**—"The quinine plantations, or quinales as they are called, which have been started in Bolivia by the Germans, are usually found on rough and broken mountain-sides, and at altitudes of three thousand or four thousand feet above the sea. The trees will grow at an altitude of eight thousand feet, but flourish best at an elevation of about four thousand feet, for they require a great deal of sun, rain, and wind to reach perfection," writes William E. Curtis in the *Chicago Record.* "Most of the groves have been raised from the seed, which is gathered in the early summer months, and planted in hot-houses. When the plants are about six inches high they are transplanted upon the hillsides, which have been cleared of underbrush and ploughed up beforehand so that the young roots can secure the benefit of all the moisture and plant food in the soil and the heat of the sun.

For shelter they are partially covered with twigs, straw, or other light stuff which also serves to keep the moisture and heat in the ground. After about two years this shelter is raked off; the plants are carefully inspected, and those which are not promising are replaced by new ones. The ground around them is kept clear of weeds, and the young trees are carefully trimmed twice a year. In five or six years the tree will have reached the height of twelve or fourteen feet, and its trunk will be straight and slender, with a diameter of about six inches. It resembles the orange tree in size and shape and peculiar gloss of the leaves. Two or three times a year three or four slips of bark above two inches wide are cut from the trunk and thrown upon a paved yard to dry. As the moisture evaporates they curl up like cinnamon. Within a year or so, nature replaces the bark that has thus been stripped off, and the tree is stripped again in other places. As it grows older smaller strips can be taken from the stronger branches, and a mature tree will produce an annual average of about four pounds of bark. The bark dries in a few days, and is packed for shipment in rawhide bales."

**Cerebro-Spinal Fever at Omdurman.**—The *Indian Medical Gazette* remarks in an editorial comment that from time to time notices have appeared in the papers regarding outbreaks of fever in the neighborhood of Omdurman, among the native population of the Ghezirah and the Soudanese troops stationed there. These outbreaks are referred to in Slatin Pasha's book, and the disease is described as typhus fever. From a report by a medical officer of the Egyptian army, which I have recently had an opportunity of reading, it appears that the epidemics in question which prevail mostly in autumn are epidemics of cerebro-spinal meningitis. The occurrence of this disease in this locality and on such a large scale constitutes a new and interesting fact in epidemiology.

**Effect of Bullet Wounds in South Africa.**—The New York *Times* says: "Some of the wounds inflicted on the British soldiers are of an extraordinary nature. The Mauser bullet makes a clean perforation of bone and muscle. Soldiers shot through both cheek-bones have lost the sense of smell and taste, but are otherwise quite well. Most of the wounds are in the hands and arms."

**Water Filters for China.**—Consul Fowler writes under date of April 22d as follows: "When in Port Arthur last November, I noticed the soldiers drinking out of large jars, or kongs, water which was unfiltered and certainly dangerous. It occurred to me that if American manufacturers could sell a good cheap filter, or, better still, small condensers for condensing either fresh or salt water, an immense market would be opened to them, not only among the Russian troops but at Wei-hai-wei, and among the Germans at Kyao-Chau, not to mention foreigners and even Chinese elsewhere in this empire, who now depend upon muddy river or rain water for all purposes."

**Propagation of the Plague.**—As to the means of propagation of the plague they are many. The poison may infect a wound or scratch; it may be ingested in food; it may be simply inhaled. Dust from an infected house was sufficient to infect healthy rats; and when infected rats were shut up in one cage with healthy ones all caught the disease and died. Already in 1881 Netten, Redcliffe, and Dr. Pichon indicated that before the plague attacks men it destroys rats and mice. This was fully confirmed in 1894 by the Japanese and French bacteriologists, Kitasato and Yersin, at Hong Kong, and by Dr. Rennie of the Chinese customs in China. Masses of dead rats were seen in the streets of the infected parts of Hong Kong, and the keeper of the west gates of Canton collected and buried twenty-four thousand of these animals. Dr. Rennie also pointed out that among those inhabitants of Canton who lived in boats on the river there were no cases of plague, and he explained the immunity of the boat-dwellers by the absence of infection through rats.—PRINCE KRAPOTKIN.

**Green Oysters.**—The latest contribution to the vexed question as to the cause of the "greening" of oysters is in the form of a paper by Professors W. A. Herdman and R. Boyce, read before the Royal Society. Green oysters are much more highly prized by many consumers than other kinds, though there is a widespread opinion that the greening is injurious. It appears from the paper referred to that there are several distinct kinds of greenness in oysters, some of which, such as the green Marennes oysters, are harmless, while others, such as the green American, are not in a healthy state. Greenness of the latter kind is caused by the presence of a greatly increased proportion of copper in the oyster, but that of Marennes has no connection with copper and depends upon the presence of a particular pigment. Analysis has shown that there is more copper in the green American oyster than in the colorless one, and more proportionately in the greener parts than in those that are less green. In the case of the huitres de Marennes no connection was found between the green color and the copper or iron they contain.—*Public Opinion.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 17, 1899:

| | | Cases. | Deaths. |

### THE FORMATIVE PERIOD OF UTERINE FIBROIDS.[1]

BY GRACE PECKHAM MURRAY, M.D.,

NEW YORK,

MEMBER OF THE NEW YORK STATE MEDICAL SOCIETY; FELLOW OF THE ACADEMY OF MEDICINE; MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, OF THE NEW YORK NEUROLOGICAL SOCIETY, ETC.

IN the *International Medical Annals* of 1899 is the statement that "it cannot be said that any advance has been made in the elucidation of the causation of uterine myomata, during the last twelve months."

Dr. Henry D. Ingraham remarks: "Whatever the real cause of uterine fibroids, the question seems to be unsettled now as at any time, and although several very ingenious theories have been advanced, none has stood the test of investigation. Possibly some of the predisposing causes, such as race and age, have been determined, but as to the exciting cause nothing whatever is known."

Dr. W. S. Smith writes, in his paper, "The Origin, Nature, and Treatment of Uterine Myoma": "I am tampering with a subject in regard to which the most noted surgeons and gynæcologists have widely divergent views. Indeed, were I called upon to select from the whole realm of gynæcology the problem which has given rise to the greatest acerbity of dispute, the greatest variance of ideas, the greatest ingenuity of device, and withal the greatest fallacies of theories, I should probably turn to this."

Dr. Oscar Kottman says: "So far back as the literature of fibromyoma extends there has never been an instant of definite etiology. All possible chemical, mechanical, nutritive, hereditary, racial, and age indications have been suggested as etiological factors."

Finally, a German writer thus sums up the state of our knowledge in this discouraging manner: "Concerning the cause of the uterine myomata, we know as little as of the cause of most of the pathological new growths, namely, nothing."

It will thus be seen that any presentation of facts on so obscure a subject as the genesis of uterine fibroids cannot be without some use in solving the problem of this, the most common of all neoplasms which afflict women. Klob maintains that forty per cent. of all women who die after the fiftieth year have uterine fibroids. I think that all the writers on the subject are inclined to exaggeration in this respect. The endless discussions on the frequency of their appearance, the question of whether married women are more subject to them than single, and vice versa, from the time of Virchow and Winckel down to the present day, have been to no purpose. It would not be possible in the nature of things to determine these matters with any accuracy. Many single women, having worse afflictions than uterine fibromata, suffer in silence, and would not seek relief from a gynæcologist. And the statistics made from post-mortem examinations have little significance, as they relate to only one class of women.

The next steps in advance in the examination of these tumors were the observations made by Kleinwächter, Gusserow, Schorler, Semb, Marchesi, Curatulo, and some others, who considered the formative period of the uterine fibroma, and tried to give some idea of the progress, notably of the time of growth, but they did not consider or demonstrate any concomitant symptoms with a view to giving a clew to the causes of the production of these tumors. The result of Kleinwächter's experience may be considered negative, since he said the size of the tumor was no criterion of its age.

These ideas, with the discussion of the several theories which have been advanced, form the bulk of the literature on the subject of the formation and development of uterine fibroids to the present day. The discussion of these theories will be postponed until reviewed in the light of the cases which I have to present. Although they seem to be numerous, they can be really summed up in a very few words:

I. Cohnheim's theory, upheld by many others, that they are developed from embryonic tissue, the mesoblast.

II. Some disturbance of the nutrition of the part through interference with the blood supply. Such was Virchow's opinion, who was the first to write upon the subject. Such was Winckel's notion. Klebs thought the proliferation of connective tissue and muscular layers of certain blood-vessels made different nodules which became aggregated to make one tumor. Kleinwächter ascribed them to the formation of round cells which are found along the capillaries and produced partial obliteration of the same, and thus the nodules were formed.

III. In this day of microbes, the theory that the fibroids are due to them is not without its supporters.

My attention was first called to this subject of the development of uterine fibroids by a case which I had under observation. In 1886 the young woman, then twenty-three years old, came under my care. She was intensely nervous. While her mother was pregnant with her, she lost a little girl for whom she greatly grieved, and whose death was a great shock to her. Her father was extremely nervous and subject to headaches of a severe neuralgic type. The young woman when she came to me was in such a state of nervous hyperæsthesia and neurasthenia, that I placed her on the rest cure. She was greatly benefited by that, and also by local treatment for endometritis, anteflexion, and ovaritis. Her dysmenorrhœa was very great, and persisted even after the other troubles had been relieved. Her pain continuing, the next year I dilated and curetted the uterus. She was still suffering from dysmenorrhœa, though not of such an aggravated type; she was able to travel and go about, and was helped by wearing an anteflexion pessary. After a long interval had elapsed since my seeing her, she returned, about two years after the curetting, complaining of great trouble. The uterus was retroflexed, and the fundus felt hard. The uterus had always the hardened feeling of a chronic metritis, but this time the fundus felt harder than formerly. She could not

[1] Read before the Section of Obstetrics and Gynæcology of the New York Academy of Medicine, April 27, 1899.

go without uterine support, and as her stay in the city was only temporary I used every endeavor to find for her a pessary that she could wear. Gradually from the hardened fundus was evolved a mass about the size of a large walnut. It could be distinctly felt before it had pushed out from the uterine body, which it proceeded to do very speedily. The cases of fibroids of the fundus which act as a slung-shot, pushing the uterus now into a state of anteflexion, now into a state of retroflexion, are not uncommon, but to feel the evolution of this mass from the hyperplastic tissue of the uterus, while yet within its substance, was exceedingly interesting and instructive in relation to the fibroid formation. Speedily the mass became pedunculated, and being so dense and heavy it elongated the pedicle and fell over into the left broad ligament, so that the former anteflexion pessary could be worn again with comfort. In 1895 the patient went under the care of a Boston physician for the old endometritis and ovarian trouble. I was interested in this fibroid, and wrote to make inquiries. The doctor replied that the ovaries were inflamed and enlarged, but there was no fibroid tumor. A few months after I had the opportunity of examining the young woman, and the fibroid was not perceptible. I thought that possibly the peduncle might have become so attenuated that the tumor had dropped into the abdominal cavity. A year ago the patient was in San Francisco, and underwent ovariotomy. I at once wrote to the surgeon who performed the operation, and he replied that, in addition to the diseased ovaries, he had removed a small fibroid with a long, thin pedicle.

The second case in which a fibroid was formed, so to speak, under my fingers, was that of a young married woman about twenty-seven years of age. She had never been pregnant nor had children. She was exceedingly neurotic. She had been under the rest-cure treatment in the charge of a well-known neurologist, who sent her to me for gynæcological treatment. She had some endometritis and hardening of the uterine body. There was also shortening of the left broad ligament, the remains of an old inflammation about the ovary. She improved very much under treatment, both in regard to her nervous symptoms and the severe headaches which she had. Still the uterine trouble did not make the progress which one would have expected. The uterus became anteflexed and the fundus felt hard, but not suggestive of a fibroid. After the fibroid was pushed out from the uterus and become pedunculated, the nervous symptoms were very greatly relieved. An anteflexion pessary, which seemed to support the growth, gave comfort. This patient, as well as the former, was subject to dyspepsia and severe headaches, as well as to all the symptoms of neurasthenia.

In each of the next two cases I could not state positively that there was no growth in the uterus when I made my first examination. It was not possible to pass the sound in either case. In the first instance, the wife of a naval officer came to me last September. The uterus was enlarged and flexed backward, and was surrounded with a periuterine inflammation, which prevented my making any extensive examination. Her hemorrhages at the menstrual period were excessive. She was exceedingly anæmic, one might say exsanguinated. In six weeks gradually the fundus changed; the uterus was very much enlarged, and a mass was distinguishable, which in two or three weeks assumed the proportions of a fist. The growth was so swift and the loss of blood at the period was so great that I felt it possible that the growth might be carcinomatous in character, and I urged a speedy operation. A myomectomy was performed. The ovaries were in good condition. The recent bands and adhesions of the periuterine inflammation which I had been combating were present, but were easily separated. The cervical artery of the right side, on which was the inflammation, was large and pulsating, and was tied during the operation. The patient made a perfect recovery. Her menstrual periods have not been excessive, and the uterus is normal in size and position. She is forty-two years old, and has had two miscarriages but no children.

The second instance was that of an unmarried lady about forty-eight years old. She had had excessive menstruation for the last two years, but thought it was due to change of life. She was exceedingly anæmic when she came to me. The hymen was so small that it was necessary to incise it to make an examination, and it was some time before I could do so in a satisfactory manner. The uterus had a hard feeling; it was enlarged, and the fundus was flexed. The discharge from the uterus was thick and gelatinous. There was not much sensitiveness. After the second period I determined to remove a growth which I felt on the right wall of the uterus. I was led to believe that it was pedunculated. Upon dilating the uterus, a large amount of thick yellowish fluid came away. I found that the tumor was sessile and spread out upon the left wall. I also could feel that the uterine tissue close to it was very much thinned. A week from that time hysterectomy was performed. The mass had increased within the week to a third more in size. The portion of the uterus which might be taken for an anteflexed fundus was likewise a fibroid development. One ovary was diseased and removed. The patient made a good recovery. During the period of fibroid formation she had indigestion and dyspepsia, was nervous and sleepless. At her first menstruation, at the age of fourteen, she had had a nervous attack, and shortly afterward St. Vitus' dance. She was not nervous naturally.

The next case was that of a school teacher, who had had a very hard time. She had, when I first saw her, ten years ago, at which time she was about thirty-eight years of age, retroflexion, ovaritis, and endometritis, with some metritis. She was curetted, after her other symptoms improved, for fungoid endometritis. About two years after that, some months having passed since I had seen her, a large mass at the right, the size of a fist, was found. It was hard. It has remained about the same size for nine years. Within the last two or three years her periods have become irregular, but when it appears her flow is very profuse, but is better after application to the endometrium of iodine.

The next case was that of a married woman, who had had two children and no miscarriages. In 1892, at the age of thirty-two years, she came to me for treatment for extreme nervousness. She felt that she would go out of her mind. She had lost a dear friend, and had had other domestic tronbles. She could not sleep, and was in a profound state of neurasthenia bordering on melancholia. The question of the rest-cure came up, but she said she should go mad if shut up by herself. She had anteflexion, metritis, endometritis, and inflammation of the ovaries. The whole condition was markedly improved in a few months, and she considered herself recovered. She came to see me from time to time, but I lost sight of her from the fall of 1894 to the spring of 1896, a year and a half from the time that I had made the last uterine examination. She had been advised by a physician under whose care, for family reasons, she had placed herself, to have an operation for the profuse uterine hemorrhages which she had been having during the winter. When under ether a large uterine fibroid was discovered. She then came to me. The tumor and uterus were removed. The former was as large as a cocoanut. The patient has been well and in good condition ever since, now three years ago.

Another case was that of a married lady who had had no children. She has had possibly one or two miscarriages in the early weeks. She had anteflexion, endometritis, metritis, trouble with the right ovary and tube, and always dysmenorrhœa. She was first under treatment in 1894, at which time she was thirty-three years old. After the inflammatory symptoms were relieved she was curetted, and then felt so well that I did not see her again until the fall of 1898. She had a large mass on the right side which was very sensitive. Her flow at the periods was and is excessive. I thought at first that there might be an extra-uterine pregnancy. Her whole condition for a month or six weeks was suggestive of that, but as the weeks passed a small fibroid developed and grew to about the size of a small orange. She has been very nervous, and has had indigestion.

The next two cases were patients of mine for a long time, and I add them as illustrative of the conditions which I am describing, although the accounts of the fibroids have come to me second-hand. The first patient was a woman who first came to me in 1889, from whom I removed a polypus which blocked the cervical canal. Her uterus was enlarged, retroflexed, and the ovaries were sensitive. She improved, and the uterus was held in position by a retroflexion pessary. The uterine flow continued to be severe, and there was also dysmenorrhœa. She lived out of town, and I advised her to have treatment from her family physician. I wrote to him of her condition and laid stress on the thickened, hardened condition of the uterus, and the chronic metritis. About a year and a half ago I was told that large multiple fibroids had developed and had been removed.

The other patient, who was unmarried, came to me in 1888. She had retroflexion, endometritis, and the worst dissecting enteritis I ever knew. She brought to me a specimen of a cast that was fully three feet long. She wore a retroflexion pessary with comfort for years. In the fall of 1895 she removed to Brooklyn. She came to see me, and her condition was the same as it had been. In the spring I received a message from the physician in Brooklyn to whom I had recommended her, telling me of a fibroid tumor that was present. A year or so afterward she had it removed. After her recovery from the operation she was exceedingly melancholy, and a few months later she committed suicide.

The literature of uterine fibroids is exceedingly rich in all that relates to treatment and operative procedure, the results of medicine and electricity, and many cases have been published of specimens exhibited which have been successfully removed by the various methods. In no department of medicine or surgery has such wide progress been made as in that for the relief of the distress occasioned by uterine fibroids. Dr. Lawson Tait, and also Dr. Péan, speak of the indifference with which these tumors were formerly regarded. The latter collected a thousand cases which had been left to themselves, and said he: "I satisfied myself that the patients had led a long life of suffering and misery which often terminated in death, referable to no other cause than these so-called benign neoplasms." Hysterectomy and myomectomy have reached such a state of perfection in their execution and results, that in those cases in which the symptoms from hemorrhage and pressure demand action, one does not hesitate to elect these measures of relief. The literature and reports of cases of fibroids from their inception are correspondingly meagre. As the ounce of prevention is worth the pound of cure, what would it not mean in relation to these tumors if the conditions which lead to their formation could be discovered, and the formative period, well recognized, could give rise to successful effort for relief before needing the knife of the surgeon? It is with this idea that I offer these cases and the comments which the study of them, with the theories already held, have called forth.

Before reviewing these cases which I have just presented I was inclined to think that these tumors arose from aberrations of cell growth, possibly of embryonic origin, as Cohnheim suggests. He defines these tumors as an atypical new formation starting in a latent embryonic rudiment. Such rudiments may not be recognized in the ordinary physiological elements, and may linger for a long time in a latent state. It is only when favored by some condition such as the supply of nutriment and their relation to surrounding tissue that they begin to multiply and to form a tumor. He adds that in most cases, however, the awakening impulse is beyond our power to discover. Much discussion has been indulged in as to whether the tumors are growths independent from the structure of the uterus, as the cell growth just referred to by Cohnheim, or are developed from the organized blood clots or elaborated from the muscle cells of the uterus, the uterine parenchyma itself. The majority of authorities hold this last view. They all recognize for the most part the impulse given, which leads to their formation, as due to some disturbance influencing the blood supply. From the time of Virchow down to the present this has been taken into account. Therefore, disturbances in menstruation, dysmenorrhœas, and the like have often been found to be contributing causes. Endometritis has likewise been shown to exist in most of these instances. The cases which I have given have a value in supporting this opinion. In those cases which have not been seen until after the tumor has been formed, the question arises, How much of the inflammatory condition is due to the presence of the tumor? In all my cases extensive inflammatory conditions had been and were present. Doléris says: "In certain cases manifestly endometritis exists. The histological examination has shown this endisputably. In others we maintain there does not exist a true endometritis either clinically or histologically." Semb is likewise uncertain in this respect, but then in the twenty cases which he cites most of the tumors were developed in the long intervals which lapsed between the times of examinations. The same is true of the cases which Kleinwächter gives. Marchesi in his cases, Campe in his, and Curatulo in his, all found endometritis, and Batuand remarks: "Endometritis is an habitual complication in the fibrous tumors of the uterus of a type corresponding to location of tumor." In the nebulous expressions of almost all the writers on this subject, the influence of an inflamed endometrium, long continued and extending into the metrium, which becomes hyperplastic, can be considered almost certain in the preformative and formative stages of uterine benign tumors. This inflammatory condition must be what was intended in the loose expressions of many writers who speak of fibroids as due to "irritation." Thus say Virchow and Winckel. Routh writes: "Any circumstances which may bring about irritation and congestion of the uterus will be a cause of a fibrous tumor." According to Lisfranc a localization of congestion will develop a fibroid. Engström says conservatively: "Local irritation in the form of hyperæmia cannot be wholly without influence in myoma." Tailhefer says the causes of uterine fibroids are congestion and infection.

It is not the lighter grades of uterine inflammation that bear a relation to uterine fibroids; it is the chronic conditions which go on to hyperplasia. The cases which I have placed before you show this undoubtedly. It would be expected that such a state would accompany the tumors once formed, but it is of interest to see how in every case this condition has preceded the fibroid formation. This goes to confirm

the opinions frequently expressed by the best authorities on this subject. Virchow says that a fibroid is not a neoplasm, but a partial hyperplasia of the uterus. Roehrig speaks of the disturbances of circulation such as the rupture of interstitial blood-vessels, which he believes to be the cause of fibroids, resulting first in a notable hyperplasia, which is the same condition only diffused, and which he says bears a family resemblance to the partial hyperplasia of the fibroid tumor. The part uterine hyperplasia bears to the formation of uterine fibroids was distinctly shown in the differentiation of the growths in the two cases which I have described. It was some time before the difference between the two could be distinguished—not, indeed, until the tumor had pushed itself out from the surrounding uterine tissue.

The most interesting and convincing studies in relation to this subject are those of Dr. Keiffer, which he recently presented in a preliminary communication at a conference under the patronage of the Société Médico-chirurgicale du Brabant. In his studies on the vascular system of the human uterus he injected the blood-vessels and found points here and there in some of his specimens which did not become injected. These little centres, two, four, or six micromillimetres in size, were concentric fibrillæ. Especially around these points of muscular fibrillæ were small openings, which were the capillaries. One or two of these whorls of muscular tissue form the nucleus of the young uterine myoma. At first they are entirely non-vascular and are flattened on the muscular tissue, and vessels from it penetrate from without inward and establish a vascularity. He thinks them of vascular origin because they are found around the vessels and their branches; then, again, they are of uterine tissue and not a neoplasm. In the beginning they have no vascularity, and later the vascularity is peripheral. It is only at a later stage that they have a vascularity of their own. Their method of growth favors a vascular origin, as they increase and thicken by growth of their own tissue as well as by additions from the uterus. They have also a centripetal growth by additions from uterine tissue and also by formation of centres around their own blood-vessels. Keiffer concludes by saying that "in all our recent researches we have found an histological structure in no way differing from the uterine tissue, normal save that which relates to the concentric disposition of the fibrillæ. There is no evidence of embryonic tissue or new formation. In these researches it seems to me that we have proof conclusive of the vascular origin of these tumors, the truth of which the writers for the last forty years have felt, but have been unable to demonstrate, likewise the confirmation of the views so often tentatively advanced that the tumors were not only of the same origin as the uterine tissue, but were uterine tissue itself, taking on a new growth and becoming aberrant because of the circulatory disturbances."

This leads up to other considerations of the formative period, namely, the blood supply. It has been stated that the tumor derives its supply from one main artery of the tumor, and upon the size of this the size of the tumor depends, and also the rapidity of its growth. This is why the tumor becomes stationary after a while in regard to size. If it is subserous and grows out far enough to make pressure on the peritoneum, it can establish a blood supply from it, and thus continue to grow. From this point of view a tumor's size depends not on outward circumstances, such as pregnancy or irritation, but carries within and around it its own conditions. If in its location in the uterine tissue it obtains supply from a large vessel, it will grow rapidly; if its blood-vessel is small, it will be a small tumor. It is this fact that limits the growth of the tumor, and consequently the menopause, which has been supposed to have had such an influence upon these tumors, has had little effect. I think it a fallacy that the growth of these tumors is arrested by the cessation of menstruation. Tumors I have had under observation for years have not changed or shrunken, and I quite agree with Dr. J. C. Irish, who says: "The majority keep on growing without the least regard to the menopause. In fact, often at the time of the menopause they seem to take a new lease of life." If they increase at the time of pregnancy, which is a disputed point, it is due to the increased vascularity of the organ, and that all the muscular structure takes on a growth.

In regard to the symptoms other than uterine, the question arises if there were any which would have suggested the tumor-forming state, any different from those which generally obtained when the excessive inflammatory conditions of endometritis, metritis, and ovarian disturbances were present. The one distinguishing symptom, though common in these conditions when no tumor formation was to be considered, was the extreme nervousness, most excessive, due either to an inherited nervous condition, or one acquired because of shock or grief or other personal consideration. With one or two exceptions the nervous condition of these patients was extreme. In two of the cases the patients had had recourse to the rest cure. For one it was suggested and given in a modified form. One patient had such an extremely nervous temperament that she went into melancholia and destroyed her life after the operation. The fifth had a nervous crisis of some kind at the establishment of her menstrual periods, and afterward had St. Vitus' dance. The other three were exceedingly nervous, and had also undergone great nervous strain. Recently the theories relative to the rapid growth of carcinoma have brought into prominence the effects of the weakening of the nervous system as a predisposing cause, and call attention to the fact that cancer is often due to "the skeleton in the closet." The loss of the balancing power of the nervous force, it is said, releases the cells from the former control, and acting independently they return to the independence of original amœbæ and flourish accordingly.

Hitherto it has been thought that curetting was a procedure which would rather tend to the benefit of uterine fibroids than not. In four of my cases this was done, in two with a view to relieving the endometritis, and setting up the alterative process, akin to subinvolution, to which one looks for the removal of the hardened conditions of metritis. Some time elapsed, to be sure, before the appearance of the fibroids in these cases. In two cases in which the curetting was done for a fungoid endometritis, fibroid tumors followed in two or three years. In two cases in which curettage was practised, the tumor being already present, the growth of the tumors was really surprising. Dr. Henrotay speaks of a case in which he had performed the operation, and seeing the small growth in less than six months after, he said that the curetting had acted upon the evolution of the fibroid like a "stroke of a whip." It might be, in the instances in which uterine fibroids had developed by the circulatory disturbance, that the blood-vessels received some injuries which cut off the circulation from the muscular uterine tissue forming the centres which afterward took on the fibroid condition. In the cases in which the tumors were present at the time of the operation, it would be difficult to say whether the operation had hastened the development of the tumor by reason of concentrating the blood supply, by reducing the vascularity of the endometrium, or whether the tumor, because of the great blood supply which had been coming to it from the beginning, would have grown any way. The question is one of

great interest, and its solution would be of practical value.

**Summary of Suggestions and Conclusions.**—1. The possibility of determining definite clinical symptoms which would lead to a recognition of a distinct formative period of uterine fibroids, which might suggest a preventive treatment.

2. That the predisposing causes of race, age (other than that of adult life), or condition count for little, and the elaborate reports which form the bulk of the literature up to the present time are of doubtful value.

3. That chronic inflammatory conditions of the endometrium, uterine parenchyma, and of the ovaries and tubes are most powerful predisposing causes, and that there is a direct relation between the hyperplasia of the uterus and the formation of fibro-myomata.

4. That extreme disturbances of the nervous system precede and accompany the formation of uterine fibroids. Insomnia, headaches, and hyperæsthesia of the sensory organs are present to a greater degree than is usually found when the concomitant symptoms of the inflammatory condition of the uterus are present.

5. That the evolution of the fibroid from the fibromatous centres when it begins to take on growth is exceedingly rapid, and that it is impossible to tell the age of the growth by its size. The rapid appearance and development are the reasons why so few fibroids are seen and examined in their incipiency. That the size and rapidity of growth of a fibroid depend upon its blood supply, which is determined from the beginning by the location of the nidus, and therefore such conditions as pregnancy or the menopause could have little influence.

6. The possibility of the action of curettage as a predisposing cause for these tumors on account of the violence done to the blood-vessels, and of hastening their growth, because of concentrating the blood supply.

7. The crystallizing effect of Keiffer's experiments upon the theories in regard to the formation of fibromyomata. He has demonstrated that the blood supply is cut off from the uterine tissue, which then becomes condensed into whorls of fibrillæ which afterward develop into fibroids, obtaining their blood supply from the surrounding uterine tissue. He has shown that the tumors were composed of an histological structure in no way differing from the normal uterine tissue, save that which related to the concentric arrangement of fibrillæ. There was no evidence of embryonic tissue or new formation.

## CAN WE DIAGNOSTICATE OBLITERATION OF THE RECEPTACULUM CHYLI?

By ANDREW H. SMITH, M.D.,

NEW YORK.

Obstruction in the course of the thoracic duct produces usually such striking phenomena as can scarcely escape observation. Among these may be mentioned chylothorax and chyloperitoneum, while chyluria is sometimes present, even when there is no filarial disease. The subcutaneous connective tissue may be infiltrated with lymph, and minute fistulæ in the skin may give exit to a clear or opalescent fluid. All of these phenomena seem to require that the distal portion of the thoracic duct, or at least the receptaculum chyli, should be patent. The duct must be open to a point above the diaphragm in order that chylothorax may take place, and distention of the receptaculum seems to be necessary to effusion of chyle into the peritoneum. In these cases the process seems to be entirely analogous to the serous effusion that follows venous obstruction, with this addition, that rupture of the duct or of the receptaculum may and frequently does occur. It is also necessary that the obstruction should be somewhat suddenly produced. If there is a gradual narrowing, opportunity will be given for the establish-

ment of a collateral lymph circulation, and extravasation will not take place. In the absence of such collateral circulation it is evident that complete obstruction of the thoracic duct must prevent the absorption of the chyle from the small intestines, leaving it to pass away with the fæces. This deprives the body of the nutriment it would otherwise derive from the fatty elements of the food, and leaves it to be sustained by the proteids and the carbohydrates. The former have very little power to build up adipose tissue, and the latter, in the absence of hydrocarbons, are very largely drawn upon as heat producers, leaving a meagre surplus to be converted into fat. Hence under these conditions we should expect rapid emaciation, and this has been the result both when the obstruction has been brought about by disease and when it has been experimentally produced in animals. It is true that disease of the duct is most frequently malignant, and affects other organs, and especially the stomach; so that emaciation would be a natural consequence apart from obstruction of the duct. But it is not so rapid nor so extreme as in the cases in question. Failure of the chyle to be absorbed would naturally lead to its appearance in the stools, except in so far as it might be taken up from the large intestine. We should expect, therefore, an increased number of passages of a soft consistence and pale in color.

Quite a number of cases of obstruction are on record, but in no instance, so far as I have been able to find, is the question of emaciation as connected with the condition of the duct alluded to. In some of them marked emaciation is noted, but only incidentally, and as an item of the routine post-mortem record. In some cases distinctly chylous diarrhœa has been noted, but this is when a rupture of a lymph vessel has taken place in such a way as to open into the intestine. Two cases in which obliteration of the receptaculum took place have come under my observation.

On July 2, 1881, President Garfield was shot at Washington. The bullet entered the right side of the back, four inches to the right of the spinal column, on a level with the twelfth dorsal vertebra, and passing at first forward fractured the eleventh and twelfth ribs; then, being deflected to the left, passed through the body of the first lumbar vertebra in an oblique direction to the left, and, emerging thence, passed behind and below the pancreas, where it lodged. The ball in its course divided some of the branches of the mesenteric artery, and grazed the splenic, producing an injury of the latter which gave rise to fatal secondary hemorrhage. The cavity of the peritoneum was not opened. The wound caused extreme shock, and a prolonged period of collapse. It was not until after about twelve hours that reaction was established. From this time the condition remained favorable until July 23d, just three weeks from the time of the injury. At this date a rigor occurred, and evidences of septic infection were present from that time until death. The constitutional symptoms, however, were not severe. Even at the time of the chill the temperature remained below 102° F., and only on a few occasions thereafter it reached as high as 101° F. For much the greater part of the time, the daily maximum was 100° F. or lower. The patient took a good amount of food, mostly liquid, and consisting largely of milk in various forms. There was a period, however, beginning about August 8th, and lasting about ten days, during which the stomach was very irritable and nutritive enemata afforded the greater part of the nourishment retained. After this the stomach regained its tone to a fair degree, and the enemata were for a while suspended.

Thus it appears from the record kept by Dr. Rayburn, one of the attending surgeons, that up to August 23d the patient had taken and retained, and apparently digested, an amount of food which, while not adequate to a full nourishment of the body, was still enough to forestall any great or rapid loss of weight in a case presenting so little rise of temperature. Yet at this date, August 23d, it is recorded: "In spite of all our efforts to nourish the President, he is emaciating so rapidly that it is distressing to look at him. His weight when he was wounded was two hundred and ten pounds, and his weight now is probably not more than one hundred and thirty or one hundred and thirty-five pounds. This emaciation is accompanied by such great exhaustion as to give rise to the most gloomy forebodings on the part of his medical attendants."

President Garfield died at Elberon, N. J., on September 19th. I was present at, and took part in, the autopsy. The injury to the vertebral column was then for the first time revealed. During life it was supposed that the bullet had been deflected downward into the right iliac fossa, and the autopsy was conducted on that assumption. This was perhaps unfortunate, as it led to a removal of the stomach and intestines *en masse* at an early stage of the examination. The mesenteric attachments were severed from the spinal column by a few strokes of the knife, without any thought of the relations of the parts involved to what proved to be the seat of the most important lesion. These viscera being removed, it was seen that the bodies of the vertebræ in the upper lumbar region were embedded in a dense, almost cartilaginous mass of partly organized inflammatory exudate. This mass completely covered over and concealed the points of entrance and exit of the bullet in its passage through the bony structure. It must also have surrounded, and by its presence occluded, the lower portion of the thoracic duct, though no one present thought at the moment of even the existence of that unobtrusive canal. But within a day or two after the autopsy the thought occurred to me that the duct must have been obliterated by the pressure of the exudate, if not at first most certainly later, when the mass contracted and in some degree assumed the character of cicatricial tissue. A portion of the vertebral column with adherent soft parts had been taken to Washington for further examination, and I wrote at once to Dr. Woodward, who acted as pathologist in the case, asking him if it were still practicable to examine the specimen with reference to the condition of the thoracic duct. To this letter I received no reply, and I assume that it was received too late. For my own part, I have no doubt that whatever other factors contributed to the rapid and extreme emaciation so graphically described in the clinical record of the case, a considerable share was due to exclusion of the chyle from the circulation, owing to obliteration of the receptaculum chyli. The walls of this sac are so delicate, and the force of the lymph current is so slight, that very little pressure from without would be sufficient to accomplish this result. The effect upon nutrition in a case in which the diet consisted chiefly of milk could not fail to be disastrous. The use of nutritive enemata, composed mostly of milk, from August 14th until death, prevented the recognition of chylous diarrhœa if such was present.

On July 9, 1898, I was called to see a gentleman fifty-five years of age, whom I had met every summer for a number of years, always apparently in robust health, and who had been going about as usual up to the time of his sending for me. I had seen him almost every day for some weeks before, and had not noticed anything unusual in his appearance. I mention this to show that at that time he had not lost flesh to a noticable degree, but was still well nourished, though he had never been inclined to corpulency. Thirty days thereafter his emaciation was extreme. The history that he gave me was that for about six months he had not been quite well. He had had some epigastric pain, and his appetite had not been so good

as usual. Latterly he had suffered somewhat from nausea, and on two or three occasions had vomited. Still up to this time he had not changed his usual habits, and was able to eat a fair amount with considerable relish. His physician, a prominent practitioner in a neighboring city, had told him that he had an ulcer of the duodenum. At the time of my visit he suffered somewhat from a dull pain in the back at about the level of the first lumbar vertebra. This pain was pretty constant when the patient was in the erect posture, but was considerably relieved on lying down. Besides this there was quite a severe epigastric pain, which came on immediately whenever anything was taken into the stomach, but passed away in the course of an hour or two as the stomach again became empty. When there was nausea it was coincident with the pain, and seemed to be excited by it. Vomiting was a rare occurrence. There was decided epigastric tenderness, but no tumor could be felt. There was no enlargement of the liver. The bowels were moved twice or three times in the twenty-four hours, the stools being rather copious, of a semi-fluid consistence, and of a pale yellow color. Examination of the material obtained by the stomach tube showed absence of free hydrochloric acid, and the presence of lactic acid. The patient took an ample amount of liquid food, consisting of milk in various forms, beef tea, raw eggs, and also a little fruit. His food was seldom rejected, and never appeared undigested in the stools. A test dose of oil afforded no evidence of defective action of the pancreas. Nothwithstanding this apparently ample consumption and digestion of food, it soon became apparent that the nutrition of the patient was strikingly at fault. He emaciated with startling rapidity, and three or four weeks sufficed to reduce him to an extreme degree of attenuation. This was the more remarkable as there was very little severe pain, and a fair amount of sleep was enjoyed. As the days passed on the following diagnosis shaped itself in my mind: There was cancer of the stomach, as was indicated by the pain and tenderness and the chemical reactions, together with the age of the patient. The cancer was on the posterior wall of the stomach, as there was no tumor to be felt. There was an ulcerated surface, as was indicated by the immediate aggravation of the pain on taking food. The pylorus was not involved, as there was none of the deferred vomiting which accompanies that condition. The mucous surface of the stomach was not greatly encroached upon, as stomach digestion was complete. There was obstruction of the thoracic duct, as indicated by the extremely rapid emaciation, not otherwise to be satisfactorily accounted for, and by the copious semi-liquid stools of a pale color, such as would result from an admixture of chyle. The obstruction was at the beginning of the thoracic duct, as there was absence of chylothorax or chyloperitoneum.

Death took place on the 20th of August, forty days after my first visit. During the last two weeks an epigastric tumor was obscurely palpable. A moderate hemorrhage from the stomach occurred about ten days before death. The autopsy, which was only partial, revealed a scirrhous mass the size of a closed fist apparently springing from the tissues covering the bodies of the first and second lumbar vertebræ. This mass was so firmly adherent to the spinal column that it could be removed only by dissection. The posterior wall of the stomach was firmly adherent to this mass, and the corresponding mucous surface was ulcerated for a space about two inches in diameter. The remainder of the mucosa was normal in appearance. The pylorus was intact. The head only of the pancreas was involved in the disease. There was no fluid in either the pleural or peritoneal cavity. It was impossible to recognize the receptaculum chyli in the cancerous growth in which it was involved, but there could be no doubt of its complete obliteration.

Among the recorded cases, J. Schramm describes one of primary carcinoma of the pancreas with secondary involvement of the thoracic duct. After pain in the region of the stomach of undefined duration with emaciation, sudden swelling of the abdomen occurred. Sixteen litres of a milky fluid were withdrawn. Death occurred from acute peritonitis. There was no chylous urine. The thoracic duct was found obstructed by a carcinomatous growth throughout its whole extent.

L. Hektom's case. Primary cancer of the pylorus, secondary of the thoracic duct. Marked emaciation, swelling of abdomen, and diarrhœa were present. The patient was tapped three times with removal of five litres of milky fluid. There was chylous urine.

H. Senator's case. Primary cancer of the ovaries and uterus, secondary of the duct. There were marked emaciation, great dyspnœa, and swelling of the abdomen. Effusion of chylous fluid into the abdomen and both thoracic cavities occurred. The urine was not chylous. The duct was found carcinomatous and obstructed.

O. Leydhecker's case. Primary carcinoma of the stomach, secondary of the thoracic duct. Emaciation was marked, the abdomen was enlarged; 1,500 gm. of chylous fluid was removed from the abdomen (circumference of the abdomen 84 cm.) and 3,000 gm. more at autopsy. The pleural cavities contained opalescent fluid. The urine was not chylous. The duct was infiltrated, compressed by glands, and thrombosed.

Troissier's case. Primary cancer of the kidney and supra-renal capsule, secondary of the duct. There were marked emaciation and dyspnœa, but no chylous urine, no ascites or chylothorax. The whole length of the duct was found cancerous.

From my two cases and from the foregoing citations, it would seem that when with symptoms of disease in or about the stomach we have more rapid emaciation than can be otherwise explained, we are justified in making the diagnosis of probable obliteration of the receptaculum chyli, and that this probability will be increased to a very strong presumption if there are in addition rather copious, pale, semi-fluid passages from the bowels. Under such conditions we should not place much dependence upon fatty substances as articles of diet. Milk, so much relied upon in gastric disorders, will be useful only for the proteids and the sugar which it contains. Albuminous and saccharine or sugar-producing foods must be employed in sufficient quantity to compensate for the loss of the fats.

## THE CAUSE AND TREATMENT OF RECURRING LARYNGEAL STENOSIS FOLLOWING INTUBATION.

By LOUIS FISCHER, M.D.,

NEW YORK.

This condition is primarily caused by forcibly pushing a tube into an œdematous or infiltrated mucous membrane. O'Dwyer says that it is due to using a tube that is too large for the lumen of the larynx; usually in the hands of inexperienced operators. Metallic tubes that have been worn for a long time contain large calcareous deposits; the latter are due to a deposit of lime salts contained in the diphtheritic membrane, and when removing such a tube during extubation, the mucous membrane is easily lacerated and thus ulceration is caused. One of the most important papers given to the profession was read before the American Pediatric Society at Washington, on May 6, 1897, by the late Dr. Joseph O'Dwyer; in his paper entitled "Retained Intubation Tubes" he says: "The cause of persistent stenosis following intubation in laryngeal diphtheria can be summed up in the single word 'traumatism.' Paralysis of the vocal cords may possibly furnish an occasional exception to this rule."

Thus an injury to the larynx can be done by a tube that does not fit; it may result from an imperfectly constructed tube, or from a perfect tube that is too large for the lumen of the larynx, although proper for the age, or from a tube that is perfect in fit and make, if not cleaned at proper intervals. O'Dwyer states that the seat of the lesion that keeps up the stenosis is just below the vocal cords in the sub-glottic division of the larynx, or that portion of the organ bounded by the cricoid cartilage. Exceptions to this rule result from injury produced by the head of the tube on either side of the base of the epiglottis, just above the ventricular bands. The reasons given by O'Dwyer for the existence of the stenosis at this particular portion can best be explained by the following.

Anatomically, normally, there exists a constriction in the cricoid region. When the mucous membrane infiltrates or becomes œdematous, it swells to such an extent and only toward the centre, as the outside is surrounded by cricoid cartilage, and, while swelling toward the centre, mechanically impedes respiration, and thus calls for mechanical relief, *i.e.*, intubation. O'Dwyer states that if a tube is forced into the larynx in a case of this kind, ulceration and sloughing of the tissues are inevitable, and in some instances necrosis of the cricoid cartilage can result from interference with the circulation. Our only safeguard in preventing too much mechanical injury, as in the condition above cited, is to introduce "a tube of small calibre."

In the early stage of this form of cases the dyspnœa returns slowly. Sometimes several days or in some instances only a few hours may pass before the former condition of laryngeal stenosis is recognized and the necessity for the introduction of a proper tube is demanded. When the dyspnœa returns slowly, it means that the lining membrane of the larynx cannot swell while the tube is in position, because it is compressed between the tube and the cartilage. It requires some time for the reappearance of the œdematous tissue, which drops into the chink of the glottis and obstructs the respiration, the latter condition being mechanically prevented as long as the tube is *in situ*. Exceptional cases have been reported in which granulation tissue springs up from the antero-lateral aspects of the larynx just above the ventricular bands. O'Dwyer states that the origin of this growth is a slight ulceration or erosion of the mucous membrane at the points corresponding to the greatest transverse diameter of the shoulder of the tube from the pressure exerted during the act of swallowing.

Paralysis of the vocal cords, although known to exist, is very hard to diagnosticate without a proper laryngoscopic examination. Like other forms of paralysis it comes very late in the course of the disease, and if, after wearing an intubation tube for a short time, laryngeal stenosis recurs, it is safe to assume that paralysis of the vocal cords is not the cause of the immediately recurring stenosis.

How can we prevent recurring laryngeal stenosis in ordinary membranous diphtheria? Every tube must be introduced in the gentlest manner possible, the slightest force exerted will lacerate the tissues. It is a wise rule to remove the tube every three days; according to O'Dwyer, tubes should be removed at the end of five days to avoid irritation from calcareous deposits. These deposits will form only on metal and not on the rubber tubes. This has been pointed out by several writers, and is borne out by experience. If a tube must be introduced more than twice, the writer has adopted the plan proposed by O'Dwyer, and which is not mentioned even in recent text-books. It consists of taking a rubber tube, immersing it in a solution of hot gelatin containing five to ten per cent. of powdered alum, and thus introducing the tube with this covering of alum-gelatin. The writer has also considerable experience with the beneficial results of a ten-per-cent. solution of ichthyol and gelatin as a covering for the rubber tube. In the same manner a film consisting of gelatin or paraffin without iodoform, and europhen three-per-cent. solution, was applied in several cases with very good results.

**Specific Stenosis.**—By this is meant a laryngeal stenosis found in syphilitic children, and which is always congenital. Such cases are very uncommon and will tax the skill of many physicians. A case of this kind was seen by the writer several years ago; an infant seven months old was brought to the clinic with a history of difficult breathing, restlessness, insomnia, cough, and retarded development. The child was nursing at the breast. Its body, the arms and legs, chiefly the face, the lips, and the finger-nails were bluish; in fact, the child was in a condition of general cyanosis. The temperature of the child was normal. The pulse ranged from 154 to 164, it was small and feeble in character. The heart sounds were dull; there was a blowing presystolic murmur, which was transmitted and could be heard with great distinctness in the vessels of the neck. It was looked upon as hæmic in character. An examination of the lungs gave on auscultation loud, sonorous râles, which at times disappeared and gave place to normal vesicular breathing. There was no expectoration. The child had a short, explosive cough several times in a minute, which on expiration gave a peculiar croupy sound, and on inspiration made a loud, rattling, rough sound. That a constant irritation was present was shown by the fact that the child had paroxysms of cough which did not abate night or day, and was not relieved by lying on the side, lying on the back, or by the child being held in a sitting position or by traction on the tongue. The stomach seemed to be in a fair condition, although there was occasional vomiting. The stools were yellowish (mustard-like) in character, and seemed to be thoroughly well digested. From the history of the child's mother I learned that from the first week after birth the cough had been present, which had continually grown worse, and at the time of writing was so bad that the mother determined to have it operated upon if necessary. Several attempts at a laryngoscopical examination were made, but these were all ineffectual in spite of a thorough cocainization of the parts. On introducing the finger nothing abnormal could be felt. The case was referred to Dr.

C. C. Rice, and he agreed with the writer that we were dealing with a case of sub-glottic stenosis, which could be relieved only by a tracheotomy. Before the case was referred to several colleagues for their opinion, the diagnosis of syphilis had been made. The mother of the child stated that she had had several miscarriages and one prematurely born baby. The medicinal treatment consisted of calomel fumigations morning and evening at intervals of twelve hours, besides inunctions of mercurial ointment and calomel internally. The child was also seen by Dr. Freudenthal, who concurred in the diagnosis of "congenital-syphilitic sub-glottic stenosis of the larynx." It was very evident that the stenosis was too far down to be benefited by an intubation tube, and thus the case was referred for a deep tracheotomy to Dr. Beck at the St. Mark's Hospital. We recognized post mortem the condition known as diverticulum of the trachea and syphilitic ulcerations.

That good can arise in syphilitic stenosis of the larynx by heroic anti-luetic treatment, no one will question, but the fact that this child had been neglected for several months without receiving any form of treatment may also have been a factor in not permitting any benefit to arise either from the mercury applied by the massage externally, or by the calomel sublimation.

Another equally instructive case is the following: "Mary L——, seven and a half years old, complained of sore throat; she had a very high fever; her pharynx and tonsils were very much reddened; temperature, 100° F. in the mouth. She complained of pain on swallowing, and was somewhat constipated. Anorexia and headache were present. The doctor prescribed mist. rhei et soda, one teaspoonful every two hours, and cold compresses to the neck, and also ordered a gargle of tannin and glycerin. The following day the throat symptoms were not improved, and examination showed small white specks on both tonsils. The diagnosis of follicular tonsillitis was made. Instead of improving the symptoms grew worse; the child's temperature rose to 104° F., and there was a general malaise; the cervical glands were very much swollen, the voice was somewhat husky, and there was an occasional cough of a croupy character. A culture sent to the laboratory showed the Klebs-Loeffler bacilli. The croupy cough continued, and a laryngeal stenosis of such severity occurred that on the fourth day of the illness intubation was urgently called for. The child was intubated by the attending physician, the mother assisting. The tube was inserted with great difficulty, requiring over twenty introductions until the tube remained in the larynx. The stenosis was then relieved. Extubation was attempted after six days; which latter was very difficult, owing to severe coughing of blood and mucus from the mouth and nose. Stenosis recurred after half an hour, and it was necessary to reintubate. On the following day Dr. L. Fischer saw the case with me at my request."

(The above is the verbatim report of the attending physician in a case which I had the pleasure of seeing recently in consultation in Brooklyn.)

There was no question in my mind that the recurring laryngeal stenosis was evidently due to the traumatism caused by repeated (forcible) introduction of the tube, inviting ulceration by a laceration of the soft tissues. It was necessary to intubate and extubate every three days for a period of forty-nine days, until the stenosis finally disappeared. In this particular case I advised a coating of gelatin and ichthyol over the tube for the internal medication of the larynx.

There were several points of interest in this case: First, the fact that the child's throat (that is, the tonsils) on clinical examination resembled a follicular tonsillitis; this spread to the larynx, produced hoarseness, and later on a stenosis. The bacteriological report showed the presence of the Klebs-Loeffler bacilli. This is emphasized for the reason that experience demonstrates that every case of both pharyngeal and tonsillar affection should be watched, the patient isolated, and treated as though it were a "true case of diphtheria" until recovery takes place; for we know that many a simple case of so-called tonsillitis is really follicular diphtheria. Second, that portion of the clinical report dealing with the difficult introduction of the tube, which later on I learned was due to the fact that the tube used was entirely too large; the mistake made, and one that caused ulceration in the larynx, the lumen of which was probably narrowed owing to œdema and infiltration, consisted in using force.

The feeding in this case was carried on through the rectum, as it was found that swallowing liquids caused such paroxysms of coughing that we left the throat undisturbed. To overcome the nausea at each examination a four-per-cent. cocaine spray seemed to serve very well.

187 Second Avenue.

## TWO CASES OF GRAVES' DISEASE SUCCESSFULLY TREATED AS INTESTINAL AUTO-INTOXICATIONS.*

By CHARLES L. MINOR, M.D.,

ASHEVILLE, N. C.

Ever since Graves in 1835 first clearly outlined the symptomatology of the disease which in English-speaking countries bears his name, and which in Germany is called after Basedow, whose first article dates from 1840, the profession has been divided as to the etiology of this most interesting trouble, and the literature has become so large that Buschan, writing in 1895,[1] reports nearly a thousand articles as written on the malady to date, while Moebius' article in Nothnagel's system[2] refers in an incomplete bibliography to eight hundred and eighty-two.

For many years the neurogenic theory, which had the powerful support of Charcot and Trousseau, promised to supplant the earlier hæmatogenic theory in popular favor, and to win general acceptance, and such good and recent authorities as McKenzie and Ord,[3] Friedrich Kraus,[4] and Buschan[5] still support it. Since 1886, however, when Moebius first advanced his thyrogenic theory,[6] which ascribes the disease to a poisoning of the system through a diseased activity of the thyroid gland, to which the nervous symptoms are secondary, there has been an increasing tendency to its general adoption, and many prominent men have spoken strongly in its favor, among others Kinnicutt,[7] Eulenberg,[8] Wood and Fitz,[9] Hurthle,[10] Starr,[11] Nothnagel,[12] Murray,[13] Notthaft,[14] and Anders[15]; and Osler in his "Practice,"[16] and in his article on Graves' disease in Wilson's "Text-Book of Applied Therapeutics,"[17] while not committing himself, seems to give most weight to this view.

But whichever of these views we adopt—and it would seem that an unassailable case for the thyrogenic theory is made by the antithesis pointed out by Moebius between myxœdema and Graves' disease; by the pathological findings in the gland (cellular hyperplasia, new development of follicles and blood-vessels, atrophy of lymph ducts), by the results of surgical treatment (very numerous reports in recent years which need not be quoted here), by the cases of myxœdema following Graves' disease (Kowalewski, Joffroy, and Achard), by the cases of Graves' disease following acute thyroiditis,[18] and by the reported effects of ex-

* Read before the Mississippi Valley Medical Association in Chicago, October 4, 1899.

cessive thyroid feeding, notably one by Notthaft,[19] and another by Béclère,[20] there still remain many questions to be answered. We still, even if we accept this theory, cannot say whether the symptoms are the result of an overproduction of a normal secretion (hyperthyroidism) or are due to the effects of a perverted one (dysthyroidism);[21] we are still in ignorance of the primal cause or causes of such increased or perverted activity, and Kinnicutt truly says,[22] "The ultimate cause of the disease of the thyroid is still a matter of speculation."

Various authors have propounded views on this point. Many things have been held accountable for the beginning of the trouble, and each in certain cases can probably act as a causative factor of the abnormal thyroid action;[23] a uniform causation doubtless does not exist;[24] yet every addition to our knowledge in this direction is of value in aiding us to establish lines for the treatment of future cases; and it is to throw some light if possible on this question that I have ventured to-day to ask your attention to the report of two cases of Graves' disease treated, and in one case at least, if not in both, I may safely say cured, on the theory that it was dependent on an intestinal auto-intoxication.

In a fairly thorough search of the literature I find that scarcely any authors have given this question of the causative relation of intestinal toxæmia to exophthalmic goitre any attention. A few refer to the value of intestinal antisepsis, Solis-Cohen[25] and Brower[26] among others; and some remarks on dietetics are made by most, but W. H. Thomson is the only one I can find who has given it any serious attention.* His articles in the *New York Medical Journal*[27] and MEDICAL RECORD[28] are most suggestive and worth careful study. Even Bouchard in his classic book on auto-intoxication does not mention the subject; yet recalling the oft-proven virulence of the ptomains produced in the intestine, and their violent effects on the nervous vascular and glandular systems, what can be more reasonable than to infer that they have some effect in the causation of a disease often ushered in, or rather preceded, by digestive disturbances, diarrhœa, flatulence, and chlorosis; in a disease the majority of whose victims are of that sex whose bowels are so rarely free from fermentation and ptomain formation; in a disease in which Chevalier and Boinet, and Silbert,[29] have demonstrated ptomains in excess in the urine pointing to a probable fermentation in the alimentary tract; in a disease in which urticaria, angio-neurotic œdema, and dermographism, troubles so frequently associated with intestinal putrefaction, are so common?

The cases which I will now report throw, I believe, some light on this subject, and in conjunction with the large number reported by Thomson,[27], [28] justify the assertion that certain cases of Graves' disease are of intestinal origin.

The first history is as follows: the patient, Miss F. C——, aged twenty-two years, birthplace and resident till 1895, Raleigh, N. C., since that time Asheville, N. C., was first seen by me May 29, 1897. Her family history was good, and free of neuropathic taint, though her maternal grandmother was a rather nervous woman. Her childhood was healthy, with nothing to note save frequent tonsillitis. In her seventeenth year she had typhoid fever, with no sequelæ; malaria of tertian type frequently. There was no pulmonary, rheumatic, renal, cardiac, or neurotic history, and according to her elder sister's statements, which agreed with my previous knowledge of her, she was even-tempered and not excitable, and of an unusually sweet disposition. Her digestion prior to 1893 was good, though she was subject to constipation; the appetite was always capricious, and the eating very imprudent. Her sleep in health was good. Her average weight in health was one hundred and thirty pounds. Her surroundings were of the best.

Present history: This dates to the summer of 1893, when on account of numerous malarial attacks she was taken to Massanetta Springs, Va., and here for the first time began to have attacks of acute indigestion, characterized by violent pain in the lower abdomen, coming on about two hours after eating, not accompanied by diarrhœa and generally traceable to indiscretions of diet. Dr. Latimer, of Baltimore, diagnosed, as her sister tells me, malaria, and told her the patient needed exercise and diet, or, as he put it, "beef and a bicycle." The attacks continued at intervals during a school session in Paris, and after her return to America and removal to Asheville, where she had one attack so severe that she was told it had threatened peritonitis. (I may here state that I saw a sister of hers in an attack, said to be identical, which was an entero-colitis of severe form from imprudence of diet.) This was her last attack save a very slight one at Christmas, in 1896, but the flatulence persisted. At this time her complexion was still fine and clear, but in the fall of 1895, after much social overexertion, she noted that she was getting pale and felt dragged out, and had poor appetite and slight fever. While not at this time her physician, I saw her frequently, and noted the advance of what seemed to be a very typical chlorosis, so far as one could judge by inspection, and which was accompanied later on by a roughness and pimpling of her formerly beautiful skin. Her doctor advised tonics and diet, of which the heedless patient failed to avail herself with any persistency. In the fall of 1896 she first noted, as the result apparently of much exercise, which she took on her physician's advice, a rapid heart action, for which she was put to bed, but without benefit.

In January, 1897, a diagnosis of Graves' disease was made, and in February she was sent to Baltimore to be treated by Dr. Osler in a private room in Johns Hopkins Hospital. I would here say that the most careful inquiry fails to show any worry, anxiety, fright, or other such nervous shock as might be looked on as an etiological factor. Through the kindness of Dr. Osler I have obtained a copy of the notes on her case while there; these show that at that time she was complaining of palpitation, nervousness, irritability, weakness, anæmia, loss of weight (twenty pounds since July); dyspnœa, especially on exertion, and consciousness of her heart throbs. Examination showed the first sound of the heart followed by a slight whiff all over the cardiac area, but most marked in pulmonic, with no accentuation of the second pulmonic; apex in fourth space within nipple line, action tumultuous; there was exophthalmos, and the pupils were dilated. The patient was very nervous and flushed very readily; pulse from 80 to 140; temperature from 99.5° F. to 101.2° F.; respiration 16 to 24; weight one hundred and thirteen pounds (was one hundred and thirty-three pounds in July); urine normal; bowels regular.

The treatment included electricity, belladonna, digitalis, nux, ice bags, and rest, and she was discharged on March 26th, somewhat improved. In her words, "the benefit was slight but evident," and its effects were lost soon after returning home.

I took charge of her case May 29, 1897; at this time I took the above history, and noted the following findings:

Lungs, negative. Heart, a blowing systolic murmur

* Since reading this paper I have found in the *Philadelphia Medical Journal* of October 14, 1899, a reference to a paper by R. Cox in the *Montreal Medical Journal* of August, 1899, in which he reports a case which he treated on this basis successfully. The original article I have not as yet been able to get. A case reported by Allen in *The Lancet*, August 26th, and referred to in the MEDICAL RECORD of October 1st, in which the use of bile produced good results, can probably be mentioned as another.

loudest over nitral area, but not transmitted to axilla; bruit de diable in neck; noise of heart sounds heard by patient in the ears constantly; pulse 130, while at rest, regular; nervous system irritable, the patient having lost her former even temper, and being so cross as to be hard to live with; sleep poor; slight tremor of the hands. Digestive system, evidences of active intestinal fermentation with over-distended intestines; tongue coated, breath foul, bowels costive.

Moderate degree of exophthalmos, most marked on the left side; Graefe's sign absent, Stellwag's sign present, thyroid gland visibly enlarged, especially on the left side; circumference of neck twelve and one-half inches (her normal I do not know, but should judge it from her size, etc., at about eleven inches).

Skin muddy with acne eruption. Weight one hundred and twenty-three pounds. Strength poor. Hæmoglobin sixty-five per cent. Fleischl; no blood count was made.

To my knowledge the patient, who lived in a home where over-rich and highly seasoned dishes were the rule, and a simple diet the exception, was a most capricious eater, eating at any and all hours as the mood struck her; she was very fond of candy, and was with difficulty induced to obey any orders. With such a history and such findings, the diagnosis of Graves' disease needs no defence, and will not, I think, be disputed. We have a typical case with most of the classical symptoms, coming on gradually in a young girl in the footsteps of a chlorosis, which was accompanied, and probably preceded, by a marked intestinal fermentation, and which had not yielded to the best treatment along the regular lines. The problem was, then, to find a proper plan for its management, and after an unsuccessful trial of the usual remedies, as in duty bound, ice, electricity, belladonna (which gave her some comfort), arsenic, ergotin, digitalis, and lastly thymus and suprarenal extracts, from which, by the way, I got no results, I felt justified in putting into practice a treatment which I thought, if the theory of her case was right, should yield results. The facts noted above had satisfied me that there was a great probability that the disease had developed not with, but as a sequence of, the intestinal troubles and chlorosis, and that a removal of these should benefit if not cure the former. I had not at this time seen Dr. Thomson's article in the August MEDICAL RECORD, nor those in the *New York Medical Journal* of 1893 and 1896, but when I saw the former I was strengthened in the belief that I had done the right thing. I was, moreover, anxious to test it, since a rather extensive experience with the treatment of chlorosis and intestinal troubles in young girls had brought me more and more to believe that a majority of these complaints were the result of ptomaine absorption (a view advanced, as far as regards chlorosis, by Sir Andrew Clark, and which has not, I think, received the recognition it deserves), and could be cured on this basis. Now as the case in hand had undoubtedly begun as a chlorosis with marked intestinal symptoms, and as this chlorosis had been immediately followed by the Graves' disease, it was justifiable to ascribe both to the same cause.

Acting on these views I ordered a strictly regulated diet, in which almost all sugars were excluded, starches very carefully limited, as I have come to look on them as the commonest producers of fermentation; a few simple green vegetables, such as squash and spinach allowed, with underdone red meats and a little chicken, which, despite Thomson's views to the contrary, I have not found to be harmful in such cases; while tea and coffee, hot breads, made dishes, condiments, and candy were all stopped, and only the simplest cooking permitted. Meals were to be at regular hours, and during the first month I demanded quiet and repose but not rest in bed; later on allowing gradually increased walks and drives, and finally golf in increasing quantities, while all excitements and gayeties were to be shunned, and early hours kept. As to medicines, I limited them to a simple organic form of iron, the lactate and albuminate being chiefly used, and to antifermentative mixtures to be taken an hour after eating, the chief drugs of this category used being salol, resorcin, beta naphthol, subgallate of bismuth, and guaiacol carbonate, not forgetting an occasional dose of calomel. My chief reliance, however, in combating the intestinal fermentation was a modified form of lavage, which I have thoroughly tested in many cases with the best results, and which I call by the expressive, if not absolutely scientific, name of liver washing. Briefly described, the patient at bed-time lies on the right side with the hips higher than the shoulders, the right side being insisted on in order to make the flow from the splenic to the hepatic flexures easier, and with a fountain syringe allows from one quart to one gallon of hot water at from 100° to 105° F., or even hotter, to flow slowly into the rectum through the usual rectal nozzle until the whole colon is full. The larger the quantity used the better, and patients soon learn to tolerate at least a gallon. This water is to be retained for a half-hour, which at first is difficult, but soon becomes easy, and is then evacuated. Clinical experience and deductions from well-known physiological facts justify me, I believe, in claiming that a large part of the water is absorbed by the intestinal wall, reaches thus the portal blood and therefore the liver, which it washes out and stimulates to greater activity as a poison destroyer, and increases the flow of bile, thereby aiding in disinfecting the bowel, and lessening putrefaction, if the view that this is a function of this fluid be correct. Aside from this free diuresis is produced, and if the water is hot enough diaphoresis as well, thus powerfully disintoxicating the system. Certainly the results of a long use of this remedy have satisfied me that such is its effect, and certainly the case in point was no exception. The lavage I for a time ordered nightly; then at longer and longer intervals as the conditions demanded, but I did not finally stop it for about a year.

Knowing the unwillingness of the patient to obey orders, and the difficulties in her case of securing a proper carrying out of a dietetic and hygienic treatment, I had a plain talk with her in the beginning, and refused to go further without the promise of absolute obedience, which I secured, and which with occasional falls from grace was fairly and faithfully given me.

By July 12th, fermentation was less; she was less irritable, and the neck had decreased in measurement to eleven and seven-eighths inches; pulse, 112.

August 9th: Color was noted as improving, but an imprudence of diet on the 17th was followed by indigestion, and the eyes became again shiny and more protuberant, and the pulse rose to 132.

September 1st: After a more careful observation of the rules there was noted a gain of color; hæmoglobin reached eighty per cent.; the anæmic murmur was no longer to be heard; the subjective sounds in the ears were less; there was not so much fatigue on exertion, and the family noted much improvement in temper. Pulse, 104.

Another dietary indiscretion on the 20th, consisting of a dinner made up of raw tomatoes, grated corn, mutton, sweet potatoes, okra fritters, and baked apples (!!) produced, as might naturally be supposed, some return of intestinal trouble, with the other symptoms; and having read by this time Dr. Thomson's article in the August MEDICAL RECORD, I put her on a koumyss diet; but finding after a few days an inability or unwillingness to abide by it, I substituted milk, which agreed well, and which I kept her on for some weeks.

A week later the pulse was 96; the neck measured eleven and three-fourths inches; the complexion was much better; the weight was one hundred and thirty pounds.

October 2d: There was some return of flatulence. Discomfort of stomach and sense of fulness and weight aften meals were noted. The tongue was coated. Pulse, 108; and the patient was irritable. I ordered hot water before meals, and mist. rhei et sodæ.

By December 27th, she being by this time back on a cautious diet, I noted: color, good; pulse, 96; neck eleven and one-half inches; bowels regular; very little flatulence; nerves steady; appetite good.

February 17th: The pulse was 88; the neck eleven and one-half inches; weight, one hundred and thirty-three and three-fourths pounds. There was no flatulence; the color and complexion were better.

March 19th: Weight was one hundred and thirty-five and three-fourths pounds; pulse, 83. The eyes seemed entirely normal; neck, eleven and one-fourth inches; temper good; color good. She eats well and prudently; bowels regular; no flatulence; she feels strong.

April 12th: Weight, one hundred and thirty-eight pounds; pulse, 80, after playing golf all the morning; tongue clean; no flatulence; digestion good; complexion nearly as good as formerly; color admirable.

On June 9th, I noted an apparently complete restitutio ad integrum. With the possible exception of a slight remaining prominence of the thyroid, not noticeable save on close observation, all the symptoms were gone, nervous, ocular, vascular, and digestive. At this time she was allowed to go to Europe, where she has since been. I have heard from her at frequent intervals, and I am glad to say that there has been no return of any of the symptoms. The heart is normal in its activity, not being excited even by mountain climbing and bicycle riding, in which she has indulged freely; the digestion is good, the nervous system normal, and the last time I heard from her she said she feels as well as she ever did.* She will shortly be married to a foreign military officer. Let us hope married life will bring about no return of her malady, although the possibility of a future relapse cannot be ignored.

Some may doubt if the cure in this case, the completeness of which I do not believe will be disputed, was the result of the treatment recorded, or one of those fortunate remissions or spontaneous cures which sometimes come in this trouble; but I believe that from the facts presented, from the failure of other and regular treatment carried out, not only by me but by so able a man as Dr. Osler, and from the fact that during the course of treatment imprudences of diet invariably brought on a return of disappearing symptoms and relapses, which yielded to strict regimen, I am justified in asserting that this was no case of "post hoc propter hoc," and that the measures used produced the results attained.

The other case of this trouble which I will report, and which should probably be reckoned one of Marie's "formes frustes," came under my care through the kindness of Dr. Ambler while I was treating the above case, and though not reported so fully, my record of it not being as complete, was also much benefited, if not cured, by this plan of treatment.

The patient, Mrs. D——, first seen by me on September 27, 1897, was a married woman aged forty-seven years, of English parentage, but resident in America thirteen years; occupation, housekeeping. Her family history was negative; previous history entirely negative. She was married at the age of thirty-two years, and had had five children. Her last labor was five years ago, and tedious. She had a slight malarial and rheumatic history; she was not nervous till the last few years; weight in health, one hundred and forty-two pounds, at present one hundred and thirty pounds. She is a great tea drinker, but has no alcoholic habit: she is a fast eater and, as I found, a great gourmand. Her present trouble dates from May, 1897, when after a wetting she got cold, with fever and a bilious attack, and vomiting of bile, and pain at the base of the right lung in the liver region. The pyrexia lasted two weeks, and ran from 101° to 102° F. A doctor, thinking the trouble was connected with the uterus and tubes, suggested a laparotomy, but she used only hot douches, and rest in bed with diet, and got well. During July she felt poorly, and after eating she had pain in her stomach. On September 1st, she had a fluttering in the pit of the stomach, and a sinking feeling, and one night she had an attack with severe pain in the bowels, hot flushes, and a sense of impending death. At this time she called in Dr. Ambler, who told me he found her with a pulse of 160, great anxiety, and pronounced pulsation of the abdominal aorta in the epigastrium. The bowels had been loose, but were then costive. After this she had returns of such attacks, especially the tachycardia. On the 10th, when called in, I noted: pulse, 120; coated tongue; strong pulsation and systolic bruit in the epigastrium below the heart to the left of the nipple line, this pulsation being so marked as to suggest the possibility of an aneurism. Liver, normal; lungs, normal; heart, save for rapid action, normal. She confesses excessive tea habit, flatulence, and the custom of eating between meals whenever she feels hungry. Globus hystericus was present; the eyes were shiny but only very slightly prominent. The thyroid shows a medium-sized enlargement on the left side, hard to the touch, which has existed for years. The treatment was similar to that in the last case, with the addition of belladonna and digitalis on account of the tachycardia, which they helped. The improvement was marked. The attacks of epigastric pulsation and tachycardia, which had so frightened her and caused fear of death, were soon very much improved, as was also the digestion, although it was with difficulty that I prevented her from indulging her large appetite. On discharge the pulse was 80; the eyes were still rather shiny. The attacks were entirely removed. The old struma is unchanged, but in the two years which have since elapsed she has, according to her own statement recently made to me, had no trouble, and feels perfectly well.

I fully realize, gentlemen, that I am not justified in drawing positive conclusions from these two cases, but I believe that I can safely say that they show that some cases of Graves' disease at least have their origin in intestinal fermentation and the poisoning subsequent thereto; that treatment directed to removing this fermentation and this poisoning can cure such cases, and that the profession should pay more attention than they have hitherto to the intestinal condition in Graves' disease. I cannot begin to surmise what percentage of cases would present such an etiology, but from the references in the literature to the presence of flatulence and digestive disturbances in this trouble, from the large number of cases reported by Dr. Thomson, and from those symptoms of Graves' disease which, as I have already noted, are in other troubles so frequently the result of intestinal intoxication, I feel sure that their number cannot be small.

* In a letter in answer to one of inquiry on my part when I was writing this paper, and which was not received till after it was read, she reports herself as feeling extremely well; pulse 80, eyes normal, no abnormal nervousness, appetite good and steadier than formerly; no indigestion, no tremor. She rides twenty-five to thirty miles on the bicycle without any ill effects, and the only thing she can note is an occasional sense of fulness and pulsation in the throat. This letter was written in the first days of October, 1899.

The other cases that it has been my fortune to treat I have handled in the regulation way, and without, I must confess, very satisfactory results; while digestive disturbances were uniformly present, I did not give them the special attention which I did in these cases, nor had I then become as satisfied as I now am that auto-intoxication plays so large a rôle in so many different diseases, and did not therefore direct special attention to that factor.

If my contention as presented above is right, I believe it lends strength to the view so ably presented by Eulenburg[29] and Hurthle[29] who consider that the abnormal thyroid activity depends on the circulation in the blood of some poisonous product; in the cases in hand intestinal ptomains. If I am right I feel that no doctor treating this trouble can be justified in minimizing the rôle of auto-intoxication of intestinal origin in Graves' disease, and I am sure that a more careful attention to it, not only here but in many other troubles, will fully repay the physician; and I trust that those of you who have now, or shall have, cases of Graves' disease or chlorosis under your care, will give this method a fair and unprejudiced trial in suitably selected cases, and keep careful records of your work, and report them at their completion. Only thus can we expect to clear up the etiology of this obscure disease, and place it on a foundation of accurate clinical experience.

---

**Fibroma Uteri.**—Schauta's technique is so far different from the usual method, that after anterior and posterior opening of the peritoneum he stitches their edges to the corresponding edges of the vaginal walls. The broad ligaments are secured by ligatures, and he then amputates the cervix as high as possible. He does not employ forcipressure.—*The Medical Press*, August 30th.

## Progress of Medical Science.

**The Value of Urotropin in the Treatment of Certain Forms of Genito-Urinary Diseases.**—Dr. J. M. Thompson (*Boston Medical and Surgical Journal*, November 16th), from his experiences and observations on the therapeutic action and effect of urotropin in diseases of the genito-urinary tract, summarized the essential points, in brief, as follows: (1) A urinary sterilizer, antiseptic, and acidifier, prompt and reliable in action, moderate in dose, which, if adhered to, renders it both non-toxic and non-irritating to all parts of the animal economy. (2) By virtue of its peculiar affinity for the urine, into which it passes unchanged, and where it parts with formaldehyde, it is apparent that its action in genito-urinary lesions is likely to be complete and certain. (3) Its decisive and lasting effect, and especially its comparative singleness of action—which last is a most desirable property—should give it a place in the list of medicinal specifics. (4) From observations reported thus far, urotropin has appeared to be most frequently indicated in chronic disease, in which it produces exceptionally good results. (5) In the writer's personal experience the diuretic action of the drug was not marked enough to render it deserving of the claim of such virtue.

**Headaches and Their Treatment.**—Dr. T. Lauder Brunton (*British Medical Journal*, November 4th) says: The first method of treatment of headache is, of course, to try to supply the brain with healthy blood; to clear away any toxins that may be present in it; and one method of doing this I have just mentioned—namely, the administration of a blue pill and a black draught. But, more than this, we may try to give something which may have the power of counteracting these toxins or of producing elimination from the liver, and I have found by personal experience that the easy way of getting rid of the toxins or of counteracting their effect, I do not know which, is to keep up the action of salicylic acid or salicylate of sodium. So that in persons who are liable to headaches I generally prescribe salicylate of sodium gr. xv., xx., or xxx. at night, with gr. x., xx., xxx. of bromide of potassium. This mixture acts better than either salicylate of sodium or bromide of potassium alone, and it will usually prevent their recurrence in the morning. The salicylate of sodium is apt to produce a certain feeling of depression or weakness, and in order to counteract these I generally give it along with half a drachm of aromatic spirits of ammonia. It may be advisable in some patients, if you are giving the salicylate of sodium regularly, to give also a little iron to counteract the effect of the salicylate in producing anæmia. For the relief of headache occurring through inflammation of the periosteum from gouty, rheumatic, or syphilitic irritation, it is evident that one remedy is very useful—namely, iodide of potassium, which should be begun in small doses and gradually increased up to gr. x., xx., or xxx., three times a day. When we think that the pain is not of a pure nature, not due simply to dilatation of the nervous fibrils in the fibrous tissue of the periosteum, but is associated also with some change in the vessels of a nature allied to them, which we find in sick headache, the iodides may be combined with the bromide and salicylate, and in all those cases it is advisable to give some aromatic spirits of ammonia along with it in order to prevent any depression effects of the drug. Whenever you get a case of intense headache which your drugs fail to relieve, always look out for glaucoma. Even in ordinary headache you will be very apt to find the affected eye is rather tight, that the intra-ocular tension is higher than usual, but in glaucoma it is very much increased, and this will be per-

manent, and not temporary as in ordinary sick headache. In cases in which this increased tension exists you must either treat the glaucoma yourself, or have the patient operated upon by some specialist, so as to prevent the loss of the eye as well as to relieve the headache, which is very intense, and which exists along with the disease.

**The Treatment of Post-Partum Hemorrhage.**—Dr. J. Z. Currie (*Boston Medical and Surgical Journal*, November 16th) summarizes an interesting article on this subject as follows: (1) A knowledge of the source of hemorrhage is necessary to insure intelligent action. (2) All rents, when easy of access, should be repaired at once. (3) If the body of the uterus is contracted and bleeding is excessive, and in all cases of hemorrhage following placenta prævia, the general cavity should be tamponed at once. (4) If this is not successful, or if the hemorrhage is constant and not excessive, the bleeding vessels should be secured if possible, and the injury repaired. (5) If atony exists and hemorrhage is not excessive, external and bimanual compression of the uterus should be used, followed, if necessary, by hot water, vinegar, or acetic acid. (6) If not successful, or if atony with excessive hemorrhage is met with instead, tampon at once after using hot water. (7) Morphine should be given hypodermatically to check the hemorrhage, and stimulants, strychnine, and auto-infusion to overcome the effects of the hemorrhage. (8) To prevent anæmia saline solution should be used, preferably per rectum or hypodermically. Saline solution may be used by infusion also if necessary.

**The Treatment of Digitalis Poisoning; Experimental Investigations.**—Drs. J. J. Taylor and C. R. Marshall (*British Medical Journal*, November 4th) say: The treatment of digitalis poisoning must be symptomatic. We know of no antidote, in any true sense of the word, to this drug. Nor do we think we shall ever know of one. Digitalis enters very slowly into the tissue metabolism; it produces distinct structural changes, and it is slowly eliminated. It therefore possesses a most unfortunate character for action of the antidote. Apparently all that we can do is to withdraw the drug if it is being given medicinally, to clear the alimentary canal of any digitalis it may contain, and increase the rapidity of elimination by diluents; to allay sickness, to reduce arterial tension when high, procure sleep if necessary, and treat every symptom as it arises. In other words, the condition must be treated as if it were, which it is, an ill-understood disease. For the reduction of the arterial tension nitroglycerin, or an ally, is the best remedy; but with the low blood pressure, which is not infrequently present in digitalis poisoning, these substances are useless. In such cases small doses of alcohol, insufficient to produce vasodilatation, would probably prove of greater service.

**The Antenatal and Intranatal Factors in Neonatal Pathology: An Attempt to Explain the Peculiarities of the Morbid States of the New-Born.**—Dr. J. W. Ballantyne (*Journal of the American Medical Association*, November 18th) gives the following summary to his interesting article on this topic: It is clearly evident that if the characters of the diseases of the new-born infant are to be understood it is essential that account be taken not only of the fact that the infant's organism has just passed through a period of traumatism and is passing through one of readjustment to meet new requirements, but also that during the nine months of intra-uterine life which precede birth, it may have been the sphere of morbid processes which have left their impress on it. It may come into the extra-uterine environment already diseased or malformed or predisposed to some pathological development. Like pregnancy, neonatal life is an epoch which has a physiology in many respects peculiar to itself, and which borders very closely on the pathological, tending very easily to pass over into it. In a certain sense the ordinary vomiting of pregnancy is to the uncontrollable form, as the ordinary "physiological" jaundice of the new-born is to pernicious icterus neonatorum. Further, just as every woman brings with her into her pregnancy the results of her past pathological history, so the new-born infant brings with him, out of his antenatal life into his neonatal existence the effects of any morbid processes which may have attacked him in utero. In this way the pathology of pregnancy and the maladies of the new-born infant are both invested with peculiarities. The peculiarities, therefore, of neonatal diseases are not inexplicable, but are the direct outcome of the action of the antenatal and intranatal factors on the organism at this period of life.

**Further Experiments with Pane's Antipneumococcus Serum.**—Drs. J. W. H. Eyre and J. W. Washbourn (*British Medical Journal*, November 4th) report as follows: (1) The serum in doses of 1 c.c. possesses for rabbits a considerable protective power against four out of five strains of pneumococcus derived from different sources. (2) It has no protective power against one strain which in morphology, virulence, and cultural characteristics is a typical pneumococcus, and which was obtained from a fatal case of pneumonia. (3) There exist varieties of the pneumococcus which at present can be distinguished only by the action of the antipneumococcus serum.

**Detection of Small Quantities of Albumin in Urine.**—A summary of the conclusions which the writer arrives at is as follows: (1) Patients with chronic albuminuria and cylindruria are accepted as risks by life-insurance examiners, probably because of lack of delicacy of the cold nitric-acid test. (2) The cold nitric-acid test fails to detect 1 part of urine-albumin in 15,000 parts urine, Purdy's tables being taken as a basis for calculation. (3) Jolles', Spiegler's, Esbach's, and Tanret's tests, together with trichloracetic acid, give rings with urine containing alkaline carbonates, when albumin is absent. (4) The absence of albumin from such urine containing alkaline carbonates can be demonstrated by filtration, precipitation with ten per cent. of an eighty-per-cent. solution of calcium chloride, filtration, and flotation upon Spiegler's test. (5) The tests mentioned in 3, together with Millard's test, and dilute chromic-acid solution, give rings with urines not containing carbonates and which remain unclouded when heated. The size and plainness of the ring increase with the specific gravity of the urine. (6) Absence of albumin from urines, as in 5, must be proved by the heat test alone. (7) Urines which give no precipitate with calcium chloride, but which cloud slightly when heated, the precipitate being insoluble in acetic acid, doubtless contain a trace of albumin. Inasmuch as the statement has been made that nucleo-albumin is coagulated by heat in acid urine, the microscope should invariably be used in such cases. The same is true in the case of urines remaining clear when heated, but which cloud slightly on addition of dilute acetic acid. —Clifford Mitchell, *New York Medical Times*, November.

**Phosphaturia.**—Prof. G. Klemperer (*Deutsche Medizinal-Zeitung*, October 12th) says that under the term phosphaturia is understood a condition in which the voided urine frequently assumes a cloudy, milky appearance, due to the presence of earthy phosphates.

It depends upon the fact that the calcium phosphate is precipitated in the urine when the proportion of acid to alkaline phosphates is in inverse ratio; in other words, when the reaction of the urine becomes alkaline. All circumstances which tend to render the urine alkaline serve to precipitate the earthy phosphates. A vegetable diet therefore makes the urine alkaline, whereas the salts of acid plants are converted into carbonated salts. It is therefore clear why, after an excess of vegetables and fruit, phosphaturia occurs. It is furthermore known that an antagonism in the acidity of the various secretions exists. If the stomach secretes considerable hydrochloric acid, then fewer acid molecules are available for the urine; whoever voids urine one to two hours after a hearty meal, be it even composed entirely of meat, will notice a mild phosphatic cloudiness. Inasmuch as neurotic people generally urinate more frequently than persons with a firm nervous system, the former have a greater tendency to phosphaturia. It is furthermore known that phosphaturia occurs when, on account of severe vomiting or lavage, a great deal of hydrochloric acid is removed from the stomach, or when, on acount of dilatation and motor insufficiency, the acid contents are retained in the stomach for a long time. All these circumstances occur frequently in neurasthenics, and thus phosphaturia is frequently combined with neurasthenia. The object of treatment, according to Minkowski, is to increase the urinary acidity. Above all, he recommends all albuminous food stuffs—meat, eggs, cheese, cereals, leguminous substances—and warns against potatoes, green vegetables, and fruit, inasmuch as they render the urine directly alkaline. Without desiring to detract from the value of dietetics in the treatment of the condition, it is believed that the cause must first be overcome, and that treatment can be of service only when the nervous condition is dealt with, since upon the latter depend the hyperacidity and general debility. Treatment, therefore, is not easy and must not be carried out schematically. There is no general dietetic and medicinal plan applicable to all cases. The object of the physician should be to select a regimen which corresponds most closely to the nervous state of his patient; much depends upon the moral influence of the physician. The patient is to be impressed with the fact that his condition is a neurotic one, which can be benefited only by regularity in his mode of life and by assistance on his part.

**Treatment of Floating Kidney.**—Prof. E. Henoch (*Therapie d. Gegenwart*, June, 1899) says that the radical operation for floating kidney undoubtedly gives brilliant results in some cases. It is, however, not entirely harmless, and the mere fixation with suture is not always of permanent value. Again, the patients are very reluctant to undergo operative intervention, and submit only when the discomfort and pain are unbearable, a condition which on the whole is very rare. For the most part, then, we try to alleviate the condition with bandages and supports. These give the patients more confidence and support, as it were, and are therefore to be recommended.

**Treatment of Internal Hemorrhoids.**—Dr. J. Boas (*Deutsche Medizinal-Zeitung*, October 30th) says that treatment of this condition must be based upon the fact that hemorrhoids is a disease of the rectum. The idea that congestion dependent upon the heart, lungs, and liver gives rise to rectal varicosities has been disproved by numerous authors. Local causes are always responsible for the development of hemorrhoids, and treatment of these causes a cure. Among local causes those which prevent the return circulation through the portal system and vena cava naturally play the most important rôle. Rectal and perirectal tumors, the pregnant uterus, tumors of the large intestine, disease of the adnexa, stones in the bladder, intestinal ulcerations, stenosis, catarrh, etc., may give rise to hemorrhoids. The most important and benign causes, however, are those which are due to the pressure of hard and stagnated fæces upon the rectal ampullæ or sigmoid flexure. Cases also exist in which hemorrhoids develop with normal defecation, with alternating constipation and diarrhœa, or, indeed, even with diarrhœa alone. In the first instance there is present a certain hypoplasia of the venous plexus, perhaps also an atrophy of the rectal mucous membrane itself. In the latter there exists, as a rule, a more deeply situated catarrh of the large intestine or rectum under whose influence an increased congestion of the hemorrhoidal plexus might occur. Most frequently, however, there is present an habitual disturbance of defecation, particularly in the lower bowel, which in time causes circumscribed, diverticula-like fecal reservoirs. The most frequent and most satisfactory therapy lies in the treatment of the habitual constipation, in the prevention of large fecal accumulations, and this not by means of laxatives, but rather by persistent dietetic treatment which produces large and soft evacuations, and prevents fecal impaction, especially in the rectal ampullæ. Mention must here be made of the general ideas as to the value of the bland, that is, the non-irritating, diet. The "bland diet" is the one which tends most of all to keep intact the integrity of the hemorrhoids, inasmuch as it favors constipation, more so than any other. Single, long-continued, and large hemorrhages justify a relative diminution of alcohol, pepper, mustard, etc. In addition to diet, general hygienic measures must be observed, exercise, gymnastics, riding, billiards, lawn-tennis, football, etc. Herewith is included rectal toilet, cleansing of the anal portion with astringent solutions, preferably tannin or alum. Rectal enemata, with gradually elevated douche, are very serviceable. These simple measures suffice in the first stage of the affection and in the absence of complications; indeed, in a large proportion of cases the varicosities disappear altogether. Even the rectal catarrh, which the patients falsely call "catarrhal hemorrhoids," gradually disappears, once the lower intestinal tract has been cleared of the fecal accumulations, or the irritation consequent upon their decomposition. Hemorrhoids ought to be treated in their very incipiency. In the later stages, the regulation of the constipation or the cure of a constipative intestinal catarrh is more difficult, and requires the aid of laxatives and irrigations. Among the former, only such are indicated as after habitual use do no harm to the gastro-intestinal tract, produce a mild and satisfactory effect, and do not wear off too quickly. This list includes rhubarb in its various compositions, sulphur, compound licorice powder, magnesia usta, and citrate of magnesia. The dose should be as small as possible. The treatment of hemorrhoids with mineral water is very popular; the results here depend entirely upon the laxative properties of the given water as well as the local effect of the baths upon the hemorrhoidal nodules. This method seldom gives permanent results. Under the same category might be included the grape cures, which also produce a regulation of the bowel function, and thus might favorably influence the condition; once, however, the treatment is stopped, the condition recurs in the majority of cases. The success of the internal therapy of hemorrhoids depends upon the treatment of the etiological factors. If this fails, then all other intervention will have but a transitory and symptomatic effect. This brings us to the local treatment by pessaries, suppositories, and ointments. The former are of temporary value and may produce a certain amount of relaxation of the sphincter by compression of the varicosities. The suppositories and

ointments may be of service in excoriations of the varicosities and in slight hemorrhages. The following suppositories and ointments are very much in use:

℞ Chrysarobin ..... 0.08
Iodoform ..... 0.02
Extr. bellad ..... 0.02
Butyr. cacao ..... 2.
M. S. Introduce one two or three times a day.

℞ Chrysarobin ..... 0.8
Iodoform ..... 0.3
Extr. bellad ..... 0.6
Vaselin ..... 15.
M. S. Apply twice daily.

℞ Potassii iodidi ..... 2.
Iodi puri ..... 0.2
Glycerin ..... 35.
M. S. Apply.

Among complications, the treatment of hemorrhage, constriction, and prolapse are the most important. Small hemorrhages, as they occur in all well-developed cases, require no special treatment. It is quite different, however, when the hemorrhages recur, when they appear at every movement of the bowels and even independently of it, or when the hemorrhages occur infrequently, but are of such a degree as to give rise to a very marked anæmia. In the first instance, the object of treatment is to prevent venous stasis by a regulated diet and mild laxatives. If, despite normal defecation, habitual hemorrhages occur, then the fluid extr. hamamel. virg. is indicated:

℞ Extr. fluid. hamamel. virgin. ..... 100
S. ʒi. t.i.d. in a glass of water.

Suppositories might also be used. In acute and alarming hemorrhages the best treatment is tamponing of the rectum with ferripyrin, chloride of iron, or iodoform gauze. Care must be taken that the tampon reaches the bleeding point, otherwise the hemorrhage will continue. At the same time a full dose of opium is given in order to quiet intestinal peristalsis. In three days the tampons may be removed, and a dose of castor oil given. In constriction of the hemorrhoids, protection and avoidance of forcible reduction are indicated. If possible a suppository of cocaine and opium is to be introduced, in order to immobilize the lower bowel. Then, after a thorough inunction of the entire anal portion and the rectum itself, reduction of the constricted portion is carefully undertaken in the side position, if needs be with the aid of chloroform, ether, or Schleich anæsthesia. Leeches might be applied in the region of the varicosities; after sufficient blood has been withdrawn reduction is usually easy. If gangrene supervenes reduction is, of course, contraindicated, and treatment with antiseptic powders is in order. In prolapse, Esmarch's "rectal carrier" might be of service.

**The Origin of Perforating Ulcer.**—In the review of cases of mal perforans operated upon by his method of nerve elongation, Dr. Chipault stated before the Société de Neurologie de Paris, at one of its recent meetings, that seventeen were of central origin, tabes, syringomyelia, etc.; eight were in alcoholics, four in diabetics, nine were consecutive to frost bite, and eleven followed traumatic lesion, infected wounds of the sole, torn out or injured corns, becoming the starting-point of peripheral neuritis.

**Diagnostic and Prognostic Value of Adenopathies in Epithelial Cancer.**—At a recent meeting of the Société des hôpitaux, Drs. Saupault and Labbé held that adenopathies have a value only when shown to be cancerous. Adenopathies directly connected with the organ affected by cancer are not always of cancerous nature. It is only in about half the cases that they have found at autopsy or in the course of operation the ganglia corresponding to the cancerous territory invaded by the neoplasm. In the other cases the enlargement is due to secondary infection by ordinary microbes drawn from the seat of ulceration, or is due to tuberculous infection, or to a condition of functional non-activity of the ganglia, which is often observed at the onset of cancer, which should be attributed to the leucocytosis observed in this affection. Distant adenopathies, as the supraclavicular in abdominal cancer, are considered rare and of but slight clinical value unless studied histologically. No deductions can be drawn from the volume and consistence of the enlargements. In nine cases of abdominal cancer, of which eight came to autopsy, the authors found the inguinal glands unaffected in all but one instance. In the one showing an inguinal gland invaded by cancer the enlargement was so small as not to be perceptible on palpation during life. Troisier does not claim that engorgement of the supra-clavicular is surely indicative of cancer of the stomach, but believes that when we suspect abdominal cancer the enlargement of this gland is a confirmatory sign of the existence of such neoplasm.—*La Revue Médicale*, September 20th.

**A Case of Solitary Kidney Cyst.**—Dr. X. von Brackel reports, in No. 250 of the *Klinische Vorträge*, the case of a young man, eighteen years of age, who for four years had noticed a swelling at first the size of a goose egg under the ribs. Only during the last year did it seem to increase in size and become painful. The patient previous to this trouble had always been in good health, but for some time past he had suffered with constipation, and lately also from attacks of vomiting, coming on without warning and generally after meals. The diagnosis lay between pancreatic and kidney cyst. The extraperitoneal operation for kidney cyst was performed. The tumor was the size of a man's head, smooth and round. Its position was retroperitoneal, in the left side of the abdomen, extending from beneath the ribs downward almost to Poupart's ligament, to the right a little beyond the median line, to the left near the loins. The kidney was sound down to its lower pole where the cyst was attached. The other abdominal organs were normal. By means of a trocar about two and one-half litres of brownish, bloody fluid were withdrawn. The cyst was then excised without hemorrhage, not being connected with the kidney substance. The kidney was fastened to the quadratus lumborum, a rubber drain was inserted, and a dry dressing applied. During the first day the patient suffered considerably. On the evening of the second day the temperature rose to 37.8° C. (100° F.), but fell later. There was slight fulness in the abdomen; some vomiting occurred, and there was a little jaundice. These symptoms disappeared on the fourth day; the drain was removed on the fifth; the sutures were removed on the fourteenth; the patient was out of bed on the twenty-second, and on the twenty-seventh day was discharged. The wound healed satisfactorily; the kidney held firmly in position, and there was no swelling or pain. The extirpated tumor was a large unilocular cyst with smooth outer and inner walls. The kidney substance which was in contact with it was normal, and it took its origin from the normal kidney parenchyma. In the connective-tissue wall were remnants of normal kidney substance, while here and there were urinary tubules and glomeruli but no epithelium. The solitary kidney cyst is very rare, comparatively few cases having been reported. These all occurred in adults, the youngest aged eighteen years, the oldest sixty-four years. It generally develops in the outside of the organ, is considered a retention cyst, and is attached to one pole of the kidney, the contents being a bright, thin liquid, sometimes bloody, sometimes colloid. Chemical examination shows albumin, salts, and occasionally traces of urine and chalky deposits.

# MEDICAL RECORD:

New York, December 2, 1899.

## THE TUBERCULIN TEST FOR CATTLE.

THE crusade against consumption shows no signs of lagging, but proceeds with undiminished vigor. The question of the spread of tuberculosis by means of infected meat and milk has now engaged the earnest attention of the foremost physicians and veterinarians of the world for several years. Time was when such a theory would have been scouted altogether, and even at the present opinions are much divided as to the degree of infectiveness induced by these causes.

With regard to meat as a source of infection, the view taken by possibly the majority of medical authorities is that this danger has been exaggerated. In an article published in the MEDICAL RECORD of August 12th, it was pointed out that, if such be not the case, how then can the fact be explained that, although since the middle of the present century meat has been a much more common article of diet than in the first half of 1800, yet within the fifty years just past tuberculosis has not only showed no increase, but on the contrary has steadily decreased.

With regard to milk, proof of its being a potent means of disseminating consumption is definite and decided. Therefore it logically follows that if the disease can be abolished from cattle the spread of consumption will be materially curbed. It is argued that the use of the tuberculin test will at least go a long way toward realizing this object. Respecting the effectiveness of tuberculin for the purpose of diagnosing tuberculosis in cattle, the testimony in its favor is, on the whole, widespread and to the point. Professor Nocard, of Alfort, chief veterinary authority in France, is especially emphatic as to the merits of tuberculin in the detection of the consumptive taint in cattle. He says that he has personally inoculated thirty-five hundred animals, and of these only three have died, and he regards tuberculin as a most valuable test. Dr. Baug, of Copenhagen, the most renowned veterinarian in the world, declares that tuberculin is of great value as an aid to diagnosis, although it is not infallible, sometimes failing altogether, and furnishing no guide as to the extent of the disease. He has found that the disease may be present in a cow and remain latent for years, exerting no influence either upon her health or milk-producing powers. In order to carry on an effective crusade against the disease, Dr. Baug has applied the tuberculin test, subsequently separating the animals which react from those which do not. Sick animals are slaughtered either immediately or after being rapidly fattened.

*The Lancet* in its issue of October 28th says: "Mr. McLauchlan Young and Dr. S. H. Walker have recently tested some two hundred and forty cattle with tuberculin, the results being followed out by a careful post-mortem examination in each case. The conclusions arrived at were as follows: (1) Our experience confirms the generally accepted opinion that tuberculin loses its virulence when kept for any length of time. (2) When used with care and under proper conditions tuberculin, although not infallible, is a reliable diagnostic of tuberculosis in cattle, except (*a*) when the tuberculous lesion is minute; (*b*) when the disease has become generalized, especially in the case of aged and emaciated animals. (3) Tuberculous udder occurs more frequently than is generally believed to be the case. The instances where tuberculosis is present in cattle and the tuberculin does not react are probably when the fluid is not in good condition from some cause, or by reason of the lowered vitality of the animal experimented upon. That tuberculin possesses valuable diagnostic qualities has been amply demonstrated, and that its more general use would have a beneficial effect in checking the inroads of consumption cannot be a matter for doubt."

The Ohio State board of health has invited a discussion on the whole question of tuberculosis among cattle, and of the measures to be taken for its prevention. This scheme is worthy of adoption by State boards of health throughout the country, as ventilation of this kind will tend to clear up all disputed points in regard to tuberculin, as well as act as a deterrent to the dissemination of tuberculosis by the agency of cattle. The *English Veterinary* is responsible for the statement that M. Nocard and M. Roux have together set to work and discovered a new tuberculin which will cause reaction, no matter how recently Koch's fluid has been injected. This discovery will be made public in due time, and, if as effective as its discoverers assert, will remove the objection attached to Koch's tuberculin, which is declared to be unreliable after the first test, and which has in consequence led to fraudulent practices by cattle dealers.

## PAY AS YOU GO.

THE editor of *The Philistine* is not quite sure what the unpardonable sin is, but believes it to be the disposition on the part of many to avoid paying certain bills. Since this East Aurora sage was a physician (or claims to have been) before he became a book-maker, he must surely have in mind the impossibility of making patients pay, or at least of making them pay quickly. He accuses the aristocrats of being the meanest in this particular, and says those who have a Thursday and are in the set have more than others despoiled him of hard-earned dollars and even "ript his reputation up the back" when he asked for his own.

All persons who ever employ a physician should

heed his advice to pay their debts cheerfully and promptly if they would live a happy life. If they followed it the doctor could also profit by the good advice to "pay as you go" and be happy ever after. Then how much better and brighter the world would be!

## THE SHORTCOMINGS OF THE BRITISH ARMY MEDICAL CORPS.

Most of the British medical journals have raised a storm of protest against the present condition of the British army medical corps, and have severely handled Lord Wolseley for his speech of last year, in which he declared that he could place two army corps of the finest fighting material, "complete in every respect," on a given point of the coast before the navy could muster the ships to transport them from England's shores. This assertion was adversely commented upon at the time, and doubts of the feasibility of accomplishing this measure were freely expressed. On one point at least experts were convinced that Lord Wolseley spoke decidedly rashly—that is, as regards the medical equipment of two army corps. By denuding the country of the standing army, reserve, and militia, two or perhaps even three army corps might be mobilized, but when it comes to supplying these corps with the necessary complement of surgeons, those best able to judge say that it can be easily shown that Lord Wolseley's statement was fallacious. This fact is ably demonstrated in an article contributed to the *London Practitioner* last year. From this it is gathered that Great Britain's active army consists of about two hundred and twenty thousand men; first-class reserve eighty-two thousand, militia reserve thirty thousand. Of the active army India absorbs seventy-four thousand. Gibraltar, Malta, and other foreign stations require about forty thousand troops for garrison duty. Recruits of one year's service, and who are ineligible for foreign duty, take away thirty thousand. Thus it may be said that when the necessary weeding out has been done, and when the troops on foreign service have been subtracted from the total, the number of men available for Lord Wolseley's army corps would amount in round numbers to one hundred and fifty thousand. The vital questions then crop up: How are these corps provided with medical aid? And is the army medical service in a position to meet without bending or breaking the pressure that will be put upon it? According to the article in *The Practitioner* referred to above, the British army regulations stipulate that one hundred and eighteen medical officers are required in the front of the fighting line of one army corps, about fifty on the line of communication (varying according to length), about twenty-five at base—with ten per cent. added to the total for casualties—in all about two hundred. Now what is the available visible supply to meet this demand? The normal establishment of the army medical staff has been given at eight hundred and ninety. At present through mismanagement and unpopularity it is at least ninety under that strength, but as the army is being increased by twenty-three thousand men, the medical staff should really be increased another one hundred, so that the proper establishment should be one thousand, and the present deficiency is therefore two hundred. So serious indeed is the undermanning that even in peace civilian practitioners are largely employed. Of the existing eight hundred medical officers on the active list, between five hundred and six hundred are constantly serving in India and foreign stations, leaving only two hundred actually available for service with Lord Wolseley's army corps. Whence, then, can be drawn medical officers for the two army corps proceeding abroad, in order that they may be complete? No doubt a certain number of civilian medical men would volunteer for duty in the field, but they would be without special medical knowledge and could hardly be placed under martial law. The writer of the article draws these conclusions: that it would seem impossible that two British army corps can be embarked medically complete in every respect: that in a military sense two army corps could be speedily mustered "complete in every respect"; that army medical officers are available for only one army corps, and that even one army corps can be supplied with difficulty with its proper number of surgeons.

To how great extent the writer of the above was correct in his prediction has already been shown. In order to equip medically the considerably less than two British army corps now in Africa, civil practitioners have been largely called upon to meet the deficiency. It is more than likely that a still greater force will be despatched to the scene of action, so that it would seem probable that by the middle of December something like half of the surgeons with the British army in South Africa will be drawn from civil life. One good result, therefore, if nothing else, may be anticipated from the war in which Great Britain is now engaged, that is, the army medical service will be subjected to thorough and sweeping reform.

## THE SURGEON'S RESPONSIBILITY FOR THE ACTS OF HIS ASSISTANTS.

The extent of a surgeon's responsibility for the acts of a trained nurse is to be tested in a suit for damages against a leading operator of Columbus, Ohio. It appears that the patient upon whom a cœliotomy was performed ultimately died of pyæmia, resulting from a pad of absorbent gauze being left accidentally in the abdominal cavity. The cause of the trouble was not positively ascertained until the wound was reopened several months later, and the gauze in question found to be the focus of an infecting centre in the peritoneal cavity.

The surgeon in charge of the case makes the statement that at the conclusion of the operation in question he asked the head nurse, who was handling the pads, if she had accounted for all the latter that had been used. She positively replied in the affirmative, and, trusting to her knowledge of the fact, the wound was closed accordingly. In his own defence against the charge of wilful negligence he places the entire blame upon the nurse, whose business it was to be sure of what she said.

The relative responsibilities of operator and nurse are thus brought to the surface of legal discussion. There is no doubt that the surgeon is always technically accountable for anything and everything occurring during an operation of which he has charge. As the acknowledged principal in the contract to guarantee all parts of his work, he is in an equal way responsible for the acts of each and every one of his subordinates.

While it must be acknowledged that the great majority of operators are accustomed to place absolute reliance on the statements of their assistants, the practice has often proved to be extremely risky in guarding against very serious mistakes subsequently. This applies more particularly to abdominal operations than to any others.

Strange to say, in connection with the particular issue involved in the present case, there is no point in the entire and often complicated technique of intestinal surgery which is of more concern to the operator than the positive knowledge that no sponge, pad, instrument, or other foreign body is on the wrong side of the closed wound.

The great liability to such accidents is abundantly attested by many melancholy reports of preventable deaths. Thus it has been made the rule to exercise the greatest care in listing all instruments beforehand, and in checking them off afterward. While it is the business either of one of the surgical assistants or of a trained nurse to attend to this very necessary detail, and while from a moral standpoint the operator himself is not morally accountable for misrepresentation of fact in the premises, it is certainly always safer for the patient and for himself that he be personally sure that everything is right from the standpoint of his own examination.

All this is said not in any spirit of criticism of the unfortunate mishap, but rather in the hope of guarding against the repetition of like experiences in future. The operator in question did everything usual under the circumstances. Hundreds like him have run similar risks without a thought of possible trouble. The lesson, after all, is the danger of trusting to any one rather than to ourselves. Of course the operator cannot see everything nor be everywhere, but it is always safest and best for him and for all concerned to guard personally against the most probable and dangerous mistakes.

## DESTRUCTIVE WEAPONS OF WAR.

The *Medical Press* says: "If the object of war be to destroy as many of the enemy as possible, then it follows that the more effective the means of destruction employed the sooner will that object be gained. . . . In the present war at the Cape the terrible devastation caused by lyddite shells has been brought into evil prominence. The lyddite is packed in a shell and fired by a percussion fuse. It is obtained by the fusion of picric acid, which is in turn manufactured by the action of nitric acid upon phenol. Its explosion creates an area of havoc far wider than that due to the ordinary shell charged with powder and shot. In the case of lyddite the resulting deaths are for the most part due to the terrific concussion of air, which has been known to kill a man at a distance of two hundred yards. To a limited extent, therefore, the lyddite is less barbarous than the ordinary shrapnel shell, inasmuch as its victims are killed outright. Beyond a doubt in this explosive we have one of the most terrible war materials yet introduced. Yet its use has not been forbidden by the usages of civilized nations, who appear to have drawn the line as yet simply against the explosive bullet."

The Medical Record, in an editorial a short time ago, remarked in words almost identical with those with which the *Medical Press* commences, that if the object of war be to destroy, then the more destructive a firearm is the more quickly will it fulfil this object. It is interesting, too, to ponder over the fact that the most sanguinary of our modern battles are mild when compared with some recorded in ancient history. When Sulla, commanding the Roman army, met the combined forces of Macedonians and Greeks at Chæronea, the allies numbering nearly one hundred and twenty thousand, the butchery among this vast host was so great that Plutarch admits that only twelve thousand got safe away. Instances quite numerous can be brought to mind in which the slaughter in far-back times was even greater than in the above-mentioned case. The more deadly artillery and firearms are, the less ready nations will be to fight, and the nearer shall we be to peace. By these means indeed the day may come when the lion will lie down with the lamb. The logical inference, therefore, must be that the most destructive weapons of war are really in the end the most merciful, for they tend to do away with war altogether.

## News of the Week.

**More Embalmed Beef in the British Army.**—In a letter to the London *Times* of November 15th, an officer on board the transport *Nubia* asserted that "sixteen hundred rations of salt carrion, labelled 'New York, 1899,' had to be thrown overboard, as it was full of disease." He said that the packers of the corned beef and pork had salted down only "the very worst portions of very inferior beasts and pigs."

**A Meeting of Acting Assistant Surgeons** will be held at the Seventh Regiment armory, in this city, on December 5th, at 2 P.M., for the purpose of effecting organization and of taking steps to secure from Congress legislation in fulfilment of verbal promises made to them at the time their services were obtained. It is claimed that the burden of the medical and surgical work of the Spanish war was borne by the nearly one thousand acting assistant surgeons of the army. These men, most of whom were young and inexperienced in military discipline and hygiene, were for the most part competent, devoted, and brave, dealing often most successfully with new forms of disease and great sanitary problems. The vaccine corps of Porto Rico,

for example, was organized and officered entirely by acting assistant surgeons. Many promises were made to these men, which were not carried out, and it is partly to obtain the fulfilment of these that the organization is to be effected. The following is what Congress is to be asked to do, and which it is hoped it will do as a mere matter of justice: (*a*) To give to each the assimilated rank, pay, and emolument of a first lieutenant (staff) upon and for the date of muster-out, thus legally fixing his status as an officer of the army. (*b*) To give to each, conformably to the admitted verbal agreement and intentions of the surgeon-general's office, full payment for properly granted leaves of absence. (*c*) To give to each the commutation of quarters (when government quarters were not found) which was originally both stipulated and allowed, but afterward cut off. (*d*) To give to each the mileage and travel pay originally promised and enjoyed, but later by unjust discrimination disallowed and retracted. (*e*) To give to each the same rights and eligibility to pensions and to land and other emoluments that attach to assistant surgeons of the United States regular or volunteer army. (*f*) To give to each the same allowance of extra pay that was given to officers and men of the United States volunteers in the late war, viz., one month's extra pay for service in the United States and two months for service beyond seas. (*g*) To give to each preference for appointment (over those who have not had previous service) in the medical corps of the army and navy, and the Marine-Hospital corps of the United States, etc.

**The Smoke Nuisance.**—The Merchants' Association of this city has voted to co-operate with Lieutenant-Commander John C. Fremont, United States navy, who is supervisor of the harbor, in stopping this nuisance caused by the burning of soft coal by tugs, lighters, and steam craft in the harbor and in all the waters adjacent to the city. It has also promised to co-operate with the naval officer in the efforts that he is making to abolish the use of this coal in factories and buildings on the New Jersey shore, adjacent to the waters of the harbor. During October several offenders in the city were arrested and upon conviction were fined $25, and were warned that a repetition of the offence would make them liable to imprisonment. In more recent cases, for some unknown reason, a merely nominal fine of $25 has been imposed.

**Suspension of Medical Students.**—The entire senior class of the Medical School, Boston University, have been suspended from recitations and lectures by the faculty. The cause of the matter dates back several weeks ago, when some forty of the class attended a clinic at the Westboro Hospital for the Insane. On their return from the hospital to the railroad station, it is alleged that the members were noisy and indulged in horse-play. Complaint was made by the hospital authorities, but the offence was repeated on the following clinic day. The members of the class were requested to apologize, and on refusing to do so were suspended.

**A Leper in San Francisco.**—About a year ago a woman who came to San Francisco from Vancouver was found to be a leper who had escaped from Molokai. An attempt was made to return her to Hawaii on a United States transport, and when this failed the authorities endeavored to send her back to Vancouver, as she claimed to be a British subject, but this attempt was equally unsuccessful. So at last it has been decided to keep the woman in the pest house. To judge by the prominence that has been given to this case in the newspapers, one would be led to suppose that the woman was the only leper in San Francisco.

**A Traffic in Cadavers.**—The city undertaker of Memphis, Tenn., was recently arrested in St. Louis for having in his possession four trunks containing dead bodies. He told the police that he had the contract for burying the city dead of Memphis, and for some time had been selling bodies to medical colleges throughout that part of the country. His method was to pack them with excelsior in zinc-lined trunks and take them with him as baggage as far as St. Louis. From there he shipped the trunks to their destination by express. He said he had been paid all the way from $50 to $200 per body.

**Diphtheria** has appeared among the inmates of the Children's Home at Middletown, N. Y., and the institution has been placed under quarantine.

**Compulsory Vaccination.**—Six members of a so-called Christian Science Church in Americus, Ga., who had refused to submit to vaccination, were tried recently before the mayor's court and sentenced to imprisonment for from fifteen to thirty days in addition to fines running from $3 to $15. It was announced that the same sentences of fine and imprisonment will be assessed against such other members of the congregation as may refuse to obey the vaccination ordinance. Counsel has been employed to represent the Christian Scientists, and certioraries will be taken to the superior court, and it is said that, if necessary, the cases will be carried to the supreme court.

**Rules for Dispensaries.**—The special committee of the State board of charities appointed to formulate a new lot of rules for the government and licensing of dispensaries has made its report. Nine rules are laid down for the dispensaries after they shall have been licensed according to law. The first one provides for the posting of a notice to the effect that the dispensary is for the treatment solely of persons too poor to pay for medical attendance, and any other persons applying for or accepting treatment is guilty of a misdemeanor. The second rule requires the employment of a registrar, who will be the manager of the dispensary. The other rules are all relating to the treatment of patients that come to the dispensary for relief. Clinical, secular, and religious instruction may be given in the institutions, but no inmates are to be required to submit to examinations or operations for any other purposes than medical or surgical treatment.

**The Malarial Mosquito,** of the species Anopheles, has been discovered in Jamaica by Dr. Grabham, of

Kingston. As nearly a third of the hospital patients in Kingston are admitted for malaria, the results which should follow the discovery and extermination of this mosquito would be of the greatest importance to the welfare of the inhabitants of the island.

**Typhoid Fever in a College.**—About forty of the students of Kentucky University at Lexington have had typhoid fever during the past month. Two have died, but it is announced that the others are convalescent, and it is believed that the epidemic has been checked. An investigation has been undertaken to discover the cause of the outbreak.

**Dengue in the Philippines.**—Major Woodhull, chief surgeon at Manila, reports that the army in Luzon has suffered for some months past with an epidemic of dengue fever, which, while not severe, has incapacitated many of the troops. There have been few really severe cases, but a large number that interfered with duty for some days. The disease, at the date of the report, October 13th, seemed to be spreading to the parts of the island south of Manila.

**The Queen Opens a Convalescent Home.**—On November 15th, Queen Victoria paid a visit to Bristol to open the Convalescent Home at Clifton. During the ceremony of the inauguration of the home, twenty-seven thousand children sang the jubilee hymn, and an address was presented to the queen, who expressed the deep personal interest which she took in the charity, and earnestly expressed the hope that the home would contribute in no small degree to the alleviation of human suffering. The visit was made the occasion for a great display of patriotism.

**New Sanatoria for Consumptives.**—A sanatorium for the treatment of pulmonary affections, the first of the kind in Scotland, is now in the course of erection at Deeside near Banchory, a few miles inland from Aberdeen. The climate of that region is said to be exceptionally favorable, there being a large amount of sunshine, a very equable temperature, a remarkably low rainfall, and freedom from high winds. The sanatorium itself will be surrounded by pine forests. A new sanatorium has also just been opened near Hamburg. The Hamburg authorities presented the site and will pay a part of the expenses for five years.

**Medical Matters in the South African War.**—The British government has requested and obtained the services of Mr. Frederick Treves as consulting surgeon to the field force in South Africa. He is now on the way to Cape Town. Sir William MacCormac and Mr. G. Makins, the latter a surgeon to St. Thomas' Hospital, are already serving in that capacity with General Sir Redvers Bullers' army, and Mr. R. L. Swan, president of the Royal College of Surgeons in Ireland, has also volunteered his services. The fund for fitting out the *Maine* as a hospital ship now amounts to about $100,000. The last instalment of the American personnel of the ship has arrived in England. The party consisted of sixteen male nurses from the Mills Training-School at Bellevue Hospital, ten orderlies, who also act as nurses, and two apothecaries, and was in charge of Dr. Thomas Wood Hastings. The position of superintendent of the hospital ship has been offered to Dr. Julian M. Cabell, captain and assistant surgeon United States army, retired.

**Recall of a Scientific Attache.**—The scientific attaché of the United States embassy in Berlin, Professor Stiles, has been recalled because of differences with the imperial health office. It is said that Professor Stiles gave offence to the German officials because of criticism of restrictions placed upon the introduction of American food stuffs, and has in consequence been treated with great discourtesy.

**Diphtheria** has been quite prevalent in Montclair, N. J., and also in Newark during the past month. In the latter city about one hundred and fifty cases occurred during November, with a mortality of about twelve per cent. During the same month in 1898 one hundred and forty cases were reported to the board of health.

**Scientific Barbers in Missouri.**—A new law went into effect in Missouri last week, according to which every barber must be licensed by a board of examiners before being permitted to snap the scissors and draw the razor. He is obliged also to observe certain rules of cleanliness and antisepsis in order to reduce to a minimum the danger of spreading sycosis, syphilis, and other communicable affections.

**Dr. A. H. Doty,** health officer of the port of New York, returned from Europe on Saturday last. His visit was for the purpose of ascertaining what measures are taken at the ports of embarkation to prevent the shipping of immigrants ill with smallpox or other contagious disease, or who may have recently been exposed to the disease. By a system of detention and medical inspection on the other side much delay is avoided on this side, and the steamship companies are also saved the annoyance and expense of a quarantine of their vessels.

**Semicentennial of St. Vincent's Hospital.**—On Sunday last the Sisters of Charity who conduct St. Vincent's Hospital celebrated the fiftieth anniversary of the founding of that institution. The main feature of the celebration was the blessing of the new chapel in the annex to the hospital building, recently completed. Archbishop Corrigan officiated, assisted by a large number of clergymen. On Monday afternoon the Ladies' Auxiliary celebrated the institution's golden jubilee by a reception at the hospital.

**Smallpox in Kentucky.**—What is described as a very serious epidemic of smallpox prevails in several counties in the State of Kentucky. Dr. J. H. McCormack, secretary of the State board of health, who has just made a tour of the infected district, says that in a population of eighteen hundred there are fully five hundred cases in various stages of smallpox at Uniontown. There are many cases in the adjacent county. The disease has been conveyed from Uniontown to Crittenden, Hopkins, Muhlenberg, and Henderson counties. The local authorities at first concaeled the facts and denied the extent of the disease.

The State board of health has placed the town in absolute quarantine, and the local authorities have promised co-operation. The entire State is urged to enforce general vaccination.

**New York State Sanatorium for Consumptives.**—The Westchester County Medical Society has begun a movement toward establishing a sanatorium for consumptives in that county. Dr. Henry B. DeHart, of White Plains, and Dr. G. H. Porteus, of Yonkers, have been appointed a special committee to visit Albany this winter for the purpose of urging the legislature to provide for a State home to be erected in Westchester county.

**The New Jersey Sanitary Association.**—The twenty-fifth annual meeting of this association will be held at Atlantic City during the second week in December. The attendance will include many prominent physicians and officials of the various boards of health throughout the State, in addition to others interested in sanitary matters. An attractive programme has been outlined.

**The Plague.**—Upon the recommendation of the Secretary of the Treasury, the President has directed the detail of the following-named officers of the Marine-Hospital service to serve in the offices of the United States consuls at the ports named: Surgeon G. M. Magruder, London; Passed Assistant Surgeon A. C. Smith, Hamburg; Passed Assistant Surgeon Rupert Blue, Genoa, Italy; Passed Assistant Surgeon J. H. Oakley, Queenstown; Passed Assistant Surgeon E. K. Sprague, Antwerp; Passed Assistant Surgeon A. R. Thomas, Rotterdam; Passed Assistant Surgeon H. W. Wickes, Glasgow, Passed Assistant Surgeon J. B. Greene, Bremen; Assistant Surgeon H. S. Mathewson, Liverpool; Assistant Surgeon S. B. Grubbs, Havre; Assistant Surgeon W. C. Hobdy, Southampton; Assistant Surgeon G. M. Corpul, Marseilles. These details have been made because of the continued prevalence of the plague in the far East and in Portugal, its gradual spread, and the danger of its transmission to ports of the United States. These officers will advise the consuls upon sanitary matters, keep the Marine-Hospital bureau informed as to the prevalence of the plague or other epidemic diseases, and, together with the consuls, will issue bills of health to vessels leaving their respective ports for ports in the United States, Cuba, and Porto Rico. No additional cases of plague have been discovered among the passengers and crew of the *J. W. Taylor*, which arrived here two weeks ago with the captain and cook ill of the disease. The ship's cargo of coffee has been discharged into lighters and will probably be delivered to the consignees in this city. It is possible that the vessel will not be allowed to dock anywhere in the city. Dr. H. B. Geddings, of the Marine-Hospital service, has obtained from the federal court an injunction restraining the health officer of the port from interfering with him in his attempt to make an inspection of the quarantine station of this port and the steamship *J. W. Taylor*. The order is returnable December 2d. It was served on Dr. Sanborn, who is acting as health officer during Dr. Doty's absence abroad. Dr. Geddings, in his application, declared that he was ordered by the surgeon-general at Washington to make an inspection of the *J. W. Taylor* on November 20th, but was prevented from doing so by Dr. Sanborn.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending November 25, 1899. November 18th.—Surgeon L. G. Heneberger ordered to temporary duty, November 23d, in connection with the recruiting rendezvous, Detroit, Mich. November 20th.—Passed Assistant Surgeon H. N. T. Harris ordered to New York, N. Y., December 4th, for examination for promotion, and then home and to wait orders. November 22d.—Medical Inspector M. H. Simons ordered to the naval recruiting rendezvous, 117 Main Street, Buffalo, N. Y. Medical Inspector A. F. Price ordered to be examined for promotion at Washington, D. C., November 29th, and then to wait orders. Surgeon G. P. Lumsden detached from the naval recruiting rendezvous, Buffalo, N. Y., and ordered home to wait orders. November 23d.—Medical Inspector D. Dickinson detached from the naval hospital, Washington, December 1st, and ordered home and to wait orders. Medical Inspector A. F. Price ordered to the naval hospital, Washington, D. C., December 1st. Assistant Surgeon F. B. Hancock, resignation accepted, to take effect from November 25th.

**Obituary Notes.**—Dr. Henry H. Mudd, of St. Louis, died November 20th of cardiac trouble following influenza. He was born in Illinois in 1844, and was graduated from the St. Louis Medical College in 1866. He was professor of surgery and dean of this college and dean of the Missouri Dental College.

Dr. Daniel McMurtrie, medical director in the navy, retired, died in Washington, November 21st. He had been in ill health for nearly a year, but was able to attend to his duties in the Navy Department up to the time of his regular retirement in June, 1898. Dr. McMurtrie was born in Milton, Pa., sixty-three years ago. He was graduated from the medical department of the University of Pennsylvania and entered the United States service in 1861. He took part in many important naval battles. He was fleet surgeon on the Asiatic station several years ago.

Dr. Joseph G. Wallace, of New York, died on November 21st after a long illness. He was born in this city forty-four years ago, and was graduated from the Bellevue Hospital Medical College in 1877.

Dr. Edson J. Abbey, a dentist in Jersey City, died on November 22d of pneumonia. He was born in Connecticut in 1859, and was graduated from the Phialdelphia Dental College in 1887.

Dr. Sheffield W. Greene, a retired physician, died at his home in Richbury, N. Y., on November 27th, at the age of eighty-five years. He was born at Hopkinton, R. I., and was graduated from the Geneva Medical College in 1846. He served during the civil war as an acting assistant surgeon.

## Therapeutic Hints.

**Psoriasis.**—Compresses steeped in rectified spirits containing two per cent. of salicylic acid, applied nightly and covered with protective.—LAU.

**Heroin** in dose of gr. $\frac{1}{4}$, given by mistake for gr. $\frac{1}{24}$ to an asthmatic patient, was followed by prostration, cyanosis, restlessness, amaurosis, pulse of 40, and feeble heart action, convulsions of the lower extremities, axillary temperature of 96.6° F., persistent nausea, and a semi-comatose condition. Strong coffee was administered and afterward caffeine hypodermatically. Good recovery occurred, and subsequent administration of the drug in doses of gr. $\frac{1}{24}$ had no untoward effect.—*The Medical Press*, September 20th.

**Sycose**, having a sweetening power five hundred and fifty times greater than that of sugar, is the newest substitute offered in diabetic conditions.

**Sedative in Insanity.**—In excited mental states, it has been found by Bodoni (*Klin. therap. Wochenschr.*, No. 21, 1899) that methylene blue administered hypodermatically into the gluteal muscles in quantities of from gr. i. to iss. produced a marked sedative effect. It was employed in various manias as well as in melancholia, delirium, and hystero-epilepsy.

**Antidote for Nux Vomica.**—Permanganate of potassium in proportion of half a grain to the litre of water will render nux vomica, taken in poisonous dose, into a harmless compound. Subsequent stomach washings with 1 : 5,000 solutions are advised.—PARATORE, *Clin. med. Italiana.*

**Vomiting of Pregnancy.**—When uncontrollable vomiting is caused by reflex contraction of the intestinal tract, especially located in the ileo-pelvic angle of the colon, as is believed to be often the case, massage carefully carried out over this region will bring relief. —GEOFFROY, *Centralbl. für Gynäk.*, July.

**Pneumonia.**—The lung differs from all other structures in having two separate circulations, the nutritive, supplied by the left side of the heart through the bronchial arteries; and the functional, supplied by the right side of the heart through the pulmonary artery. This double circulation underlies all the phenomena of pneumonia, and must be recognized in any definition of the disease, as without it the disease itself cannot exist.—ANDREW H. SMITH.

**Heart Failure** is brought about by the continued high temperature, deranged nerve and nerve centre, and lack of nutrition, as well as the obstruction in the lung and the collection of carbonic acid. Failure of the right heart is such an alarming condition of affairs, that it must be kept constantly in mind, and taken advantage of on the slightest indication pointing in that direction. Strychnine alone, or combined with suitable doses of tincture of belladonna, is, to my mind, the best cardiac tonic we possess.—WILLIAM A. DICKEY.

**Subnasal Sycosis.**—

℞ Lanolin.,
Vaselin ..... āā 20
Glycerin ..... 10
Sacch ..... 20
Sulphur ..... 10
Zinc. oxid ..... 20
M. ft. pasta.

—DR. MENAHEM HODARA.

**Golf.**—The use of golf as a remedy in the treatment of nervous ailments of a functional character, whether they affect the mental or visceral spheres, is worthy of all consideration.— *Medical Press.*

**Chronic Buzzing in the Ears,** whether due to dry sclerous otitis or to Menière's disease, is benefited, according to Bouchard, by giving quinine.

**Suppositories in Children.**—Dr. Teissier recommends, in the *Annales de Médecine et Chir. Infantiles*, September, the more frequent administration of bitter-tasting and otherwise disagreeable medicines by the rectum. Quinine, antipyrin, creosote, iodide of potassium, etc., may thus be advantageously given. It is well to carry out an evacuation of the lower bowel by means of a simple suppository before the medicated suppository is introduced.

**Gonorrhœa.**—I have long since ceased using protargol as an injection, but use it in the form of bougie, which I have made two and one-half and four and one-half inches long. The mode of treatment I adopt is very simple, and as follows: At first a smart purge: then at night, after voiding urine, introduce one or other of the bougies, either large or small, according to circumstances, and cause it to be retained in the urethra for one hour at least, avoiding passing water before morning when possible. The next morning exactly the same process is repeated with a second bougie, and again a third at night. The second morning a mild astringent injection two or three times during the day, and a few doses of medicine, generally effect a cure in a remarkably short space of time.—J. C. RIX, *Medical Times and Hospital Gazette*, September 23d.

**Chlorosis.**—

℞ Acetate of copper (neutral) ..... 0.01 cgm.
Crystallized phosphate ..... 0.05 "
Licorice powder,
Glycerin ..... āā q.s.
For one pill. Two or three daily.

—LIÉGEOIS.

**Pulmonary Emphysema.**—1. Twenty days in each month take with each meal:

℞ Potass. iodidi ..... 10 gm.
Aquæ ..... q.s. ad 300 c.c.
S. Teaspoonful.

During the remaining ten days:

℞ Sodii arsenatis ..... 0.10 cgm.
Aquæ ..... 300 c.c.
S. Teaspoonful.

2. Every eight days at bed time:

℞ Aloes ..... 0.10–0.15 cgm.
In pill.

3. Drink milk with meals and exclude tobacco and alcohol.

4. If possible take compressed-air baths.—*Jour. de Méd. de Paris*, November 5th.

**Mixture of Bromoform with Chloroform.**—The following mixture does not precipitate with the addition of an excess of water:

℞ Bromoform ..... 1.20 gm
Chloroform ..... 0.80 cgm.
Rum ..... q.s. ad 120 c.c.
M. S. A teaspoonful contains five centigrams of bromoform.

—GAY.

**Thyroid Medication** has the drawback of producing distressing phenomena, including vertigo, sleeplessness, trembling, respiratory oppression, loss of appetite, palpitation, dyspnœa, and modification of the urine. Mabille has found, according to *Merck's Archives*, that these phenomena tended to disappear when Fowler's solution was simultaneously administered, so that large doses could be kept up. Experiments on animals seem to confirm these observations.

# Reviews and Notices.

LIFE OF GEN. NATHAN BEDFORD FORREST. By JOHN ALLAN WYETH, M.D. New York: Harper & Brothers. 1899.

TO the lengthening roll of physicians who have won, if not renown, at least an honorable reputation in literary fields unrelated to medicine, must be added the name of the author of this valuable contribution to the history of the Civil War—or rather, we should say, has been added, for the interesting war sketches which have appeared from time to time in the magazines, and which were the forerunners of this now completed work, have already delighted thousands of readers and introduced to them a new historical writer. The part of General Forrest's life with which this book chiefly deals is that from June 14, 1861, when he enlisted in a Tennessee regiment, to May 9, 1865, when he announced to the troops under his command that the Union forces had triumphed and the Confederacy was no more. The story of this strong man, who—Dr. Wyeth would have us believe, and nearly but not quite persuades us—was one of the great generals of history, is of absorbing interest, and is told by one endowed with rare descriptive powers and a writer of vigorous and limpid English. With all the author's unconcealed admiration of the subject of his biography, he does not gloss over his faults nor exaggerate his virtues, but tells the story with a manifest effort to be impartial, in which he is in the main successful. He lapses, however, in his account of the taking of Fort Pillow, which is too much in the nature of special pleading. The responsibility for that fearful carnage has been fastened upon General Forrest by his own despatches, and Dr. Wyeth cannot wipe the stain of it from his memory. The book contains many portraits of the officers who served at various times under Forrest, and also illustrations by Thulstrup and others. It has no index—a serious omission in any work of an historical or biographical nature.

THE JOHNS HOPKINS HOSPITAL REPORTS. Vol. vii., Nos. 5, 6, 7, 8, 9. Contents: Operations on 459 Cases of Hernia, from June, 1889, to January, 1899, with the Special Consideration of 268 Cases operated on by Halsted's Method, and the Transplantation of the Rectus Muscle in Certain Cases of Inguinal Hernia. By J. C. BLOODGOOD, M.D. Baltimore: The Johns Hopkins Press. 1899.

THIS volume of reports from the Johns Hopkins Hospital contains an exhaustive consideration of all the cases of hernia operated upon in that institution during ten years. There is a careful clinical and statistical analysis of all the cases, many of which have been traced for a number of years. The consideration of the two hundred and sixty-eight cases operated upon by Halsted's method certainly justifies the confidence expressed in it. We note that excision of the veins of the cord is not done as a routine procedure, but that its adoption is left to the requirements of the individual case. The series of plates illustrating the Halsted operation are excellent. Silver wire certainly gets a very strong indorsement as a suture material from the surgeons at the Johns Hopkins Hospital, and their experience with it in hernia operations has been very satisfactory. It is a matter of regret that careful reports like this volume are not more frequent from our large hospitals, so that we might compare the results of other operations for hernia from correspondingly extensive and accurate series.

A MANUAL OF DISEASES OF THE NERVOUS SYSTEM. By SIR W. R. GOWERS, M.D., F.R.C.P., F.R.S., Consulting Physician to University College Hospital, Physician to the National Hospital for the Paralyzed and Epileptic, Queen Square. Third edition, revised and enlarged. Edited by SIR W. R. GOWERS and JAMES TAYLOR, M.A., M.D., F.R.C.P., Senior Assistant Physician to the National Hospital for the Paralyzed and Epileptic, Queen Square, Physician to the Northeastern Hospital for Children and to the National Orthopædic Hospital. Volume I., Diseases of the Nerves and Spinal Cord. With 192 illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

THIS, the third edition of Gowers' text-book, differs very little from other editions, in at least one respect. It remains the classic that it has always been. Unlike many other later editions of well-received works, it has been thoroughly revised and brought in accord with modern teachings. To attempt to characterize its special features would be a work of supererogation, since the entire neurological world and the greater number of general practitioners are already aware of its merits, both from the standpoints of the acuteness of the author's observations and from the philosophic grasp of general features which he shows in his descriptions of diseased conditions. In a number of minor details, more particularly in the discussions on minute anatomy and pathological histology, there are grounds for criticism, but most of these are concerned with questions which are technical and clinically non-essential, or are still undecided by microscopical research. Though the book is well printed on excellent paper and bound satisfactorily, its appearance is somewhat marred by a number of wretched illustrations. In this respect the present edition is a great advance over those of previous years, but there is still room for improvement in this small detail.

SCHLEIF'S MATERIA MEDICA AND THERAPEUTICS. A Manual of Materia Medica, Therapeutics, Medical Pharmacy, Prescription Writing, and Medical Latin. For the Use of Students and Practitioners of Medicine. By WILLIAM SCHLEIF, PH.G., M.D., Instructor in Pharmacy in the University of Pennsylvania. Philadelphia and New York: Lea Brothers & Co.

THIS red-covered volume of three hundred and fifty-two pages is one of the series of "pocket text-books" edited by Bern. B. Gallaudet, of New York. Though rather large for any but an ulster pocket, the title indicates that it isn't an overweighty volume, which is in its favor. In construction and substance it differs but little from a number of other works embracing the same general topics, but in just these subjects new works have to be brought out at frequent intervals, to give the new students the most recent additions to the old. This has here been done. The general features of conciseness and assimilable form will make the book acceptable to students especially. The practitioner who reads journals will scarcely need such a work.

THE NERVOUS SYSTEM AND ITS CONSTITUENT NEURONS: Designed for the Use of Practitioners of Medicine and of Students of Medicine and Psychology. By LEWELLYS F. BARKER, M.B. Tor., Associate Professor of Anatomy in the Johns Hopkins University, and Assistant Resident Pathologist to the Johns Hopkins Hospital. With 2 colored plates and 676 illustrations in the text. New York: D. Appleton & Co. 1899.

IT is not often that it falls to the lot of the reviewer to be filled with admiration, wonder, and delight in the pursuit of the functions pertaining to his office, nor does it always appear seemly for him to wax enthusiastic in his recognition of such a work, even though it be out of the ordinary run of text-books. We believe, however, that in the present volume we have a classic on the minute anatomy of the nervous system that is highly creditable to the author, to the university for which he labors as a teacher, and to American scholarship in general. We do not know of another work, published in any language, that we consider its equal. Stated in general terms, it is the most recent and authoritative expression of the summary of modern neurological teachings bearing on the particular field of the minute anatomy of the nervous system of man. Those readers of the series of articles appearing in the *New York Medical Journal*, 1897–99, who have watched the gradual development of the author's work and have thus come to appreciate its qualities, will be impressed on seeing the completed work. It is an entirely new creation, even when viewed from the author's early standpoint as outlined in that publication. To those who have not enjoyed the privilege of such reading, the work must come as a model of technical, scientific presentation. The author has developed his theme in such an attractive form, from the literary, technical, and pictorial points of view, that not only the neurologist but also the student of general medical science must enjoy and value highly the comprehensive presentation of such an intricate subject. The subject matter is treated of in five sections. In the first of these, the history of the development of the neuron concept is traced in a very interesting manner; the external and internal morphology of the neuron is then very exhaustively and critically described in the succeeding two sections.

Section IV. traces the development of the nervous system, presenting the histogenetic relations of the neurons. Section V. is a most able arraying of facts and hypotheses bearing on the physiological and pathological processes of the neuron units. The final section (eight hundred pages), including two-thirds of the whole volume, discusses the grouping and chaining together of the neurons. We feel that the work so far excels anything of its kind that it merits a wide and cordial reception. No worker in the fields of anatomy, neurology, psychiatry, psychology, and pedagogy can afford not to profit by its teachings, and it can safely be recommended to the general practitioner, by reason of its pleasing literary style, even though it deals with a subject technical to a degree. It should not be omitted that the publishers deserve most hearty commendation for their part in the production of such an excellent volume.

ARCHIVES OF THE ROENTGEN RAY. Edited by THOMAS MOORE and ERNEST PAYNE, with an editorial committee. Philadelphia: W. B. Saunders.

VOLUME iv., No. 1, of this journal, which is the official organ of the Roentgen Society of London, contains the usual amount of interesting matter. There are many radiographs in illustration of Mr. J. Lynn Thomas' paper on Colles' fracture. The illustrations of high frequency apparatus as applied to shells is also of interest. The radiograph of an injected infant, showing blood-vessel distribution, points to a method of demonstration to students which might supplant older means. This quarterly is keeping up its early reputation, and must prove of use to the increasing number of those employing the *x*-rays.

## Clinical Department.

### CÆSAREAN SECTION WITH RECOVERY OF MOTHER, AND CHILD SAVED.

By JAMES BYARS, M.D.,

COLUMBUS, TEXAS.

THIS is a case of a young woman whom I had personally known for many years and who had borne an excellent reputation, up to the time of the operation. Miss X——, twenty-six years of age; weight in health one hundred and thirty-six pounds, at the time of operation one hundred and sixteen pounds; height five feet seven inches. At presentation for treatment she was sallow, anæmic, and generally run down. The urine was highly colored and scant; specific gravity, 1.025; increase of phosphates, bile, and uric acid; neither albumin nor sugar. The tongue was heavily coated, the patient had a little fever in the afternoon of each day continuously for several months preceding the time of the operation. It was a typical case of chronic malarial poison. She gave the following history. About fourteen months ago she fell half-way down a flight of stairs, and was confined to her bed for several days afterward, from bruises and pains referable to the abdominal region; she felt "as if something had torn lose inside of her." She had profuse sanguineous discharges from the vagina for some time after the fall; later these discharges ceased entirely, and she had not menstruated for ten or eleven months when I saw her. Two months after the fall she "felt a lump in her side," as she described it, which for the last six weeks had grown very rapidly, and was very painful at times. The patient fainted frequently; she had had no evacuation from the bowels for four months unless prompted by strong purgatives; complained of pain in the right hip and thigh; appetite poor. I informed her of the necessity of an examination as to the tumor, to which she readily assented. Upon palpation, I found a tumor of the abdomen of elastic, spongy feel, of semi-solid consistence, extending two-thirds of the distance from the pubis to the umbilicus; of ovoid shape and occupying the middle line. I could not make out the outlines of the tumor well, on account of the distention of the intestines. The abdominal superficial veins were not enlarged, and, except for a considerable increase of pigmentation of the skin, there was nothing unusual. The breasts and papillæ were enlarged, the nipples erect, and the areolæ deeply pigmented. I attempted to examine her per vaginam, and as soon as my finger entered it impinged upon a round, firm body, low down in the pelvis, which I took to be the virgin uterus; but before I could make out what it was, she became greatly excited, and cried out, and pulled away from me, so that I did not attempt to make a further examination. I inquired if she had ever experienced any movement in the tumor, and she said only a throbbing pain when she was lying on her back, and she felt no uneasiness at any other time. I concluded that I had an ovarian cyst to deal with, and the danger of rupturing being great on account of the rapid growth, I advised an operation, the sooner the better. With her consent I secured, in a private residence, a suitable room and prepared for the operation, which took place on December 21, 1898.

The towels and open cheesecloth necessary were boiled in a solution of caustic soda, then thoroughly rinsed in hot water, and hung up to dry; when dry they were pressed out with a hot iron; the towels were folded square; gauze was cut in pieces half a yard in length, folded in squares, and each square was snugly pinned with a safety pin. The towels and gauze were then packed in a perfectly clean sheet, pinned up with safety pins, placed in a perfectly clean pan, and subjected in a bake-oven to a dry heat of high temperature for two and one-half hours. These were not removed from this sheet until ready for use, but when needed they were placed in a hot five-per-cent. solution of carbolic acid. Silk ligatures wrapped on glass rods, as well as the instruments, were boiled for three hours, then lifted out with sterilized forceps; the silk ligatures were dropped into absolute alcohol, and the instruments placed in five-per-cent. aqueous solution of carbolic acid, where they were allowed to remain until they were ready for use. On the evening before the operation, the patient was given a large enema, thoroughly scrubbed, shaved, and aseptically dressed. On the morning of the operation a large enema and a vaginal wash were given. In the operation I was assisted by Dr. C. Ralph Byars, and Dr. John H. Bowers who gave the chloroform, and one untrained nurse. While the patient was being placed under the influence of the anæsthetic, the operating-table was brought in; a plain board table, three and one-half feet high, five and one-half feet long, and twenty-six inches wide, covered with a quilt and clean sheet. The patient was lifted upon the table; the legs were wrapped in a clean blanket, and the clothing was removed from the field of operation. The abdomen and sides were again thoroughly scrubbed with Johnson's ethereal soap and warm water, and then cleansed with equal parts of ether and alcohol. The field of operation was surrounded with towels wrung out of hot carbolized water; the hands and arms of the operator and assistants were thoroughly cleansed with soap, chlorinated lime, and bicarbonate of soda, carbolized water, and lastly with ether and alcohol in equal parts.

An incision was made along the linea alba, commencing three inches above the pubis, and enlarged toward the umbilicus for four or five inches to enable me to introduce the hand easily. The hand was introduced inside the abdominal cavity, and swept over the tumor in order to determine whether or not there were adhesions or dislocation of the intestines. Finding nothing abnormal the incision was enlarged, by dividing between the fingers downward within two inches of the pubis, and upward by cutting around the umbilicus till three inches above. The tumor was turned out, and

the abdominal walls were tucked beneath it to prevent soiling of the abdominal cavity as much as possible. A medium-sized trocar was pushed through the wall of the tumor to evacuate its contents, but of course nothing but blood escaped. The trocar was then withdrawn, and the bleeding point caught up with forceps by Dr. Byars, and dropped. I then made a transverse incision of about six inches with one stroke, cutting through the uterine wall, superior surface of the placenta, and disclosing the child's buttock. Then I realized that I had operated on a gravid uterus instead of a tumor. I caught the uterus with my left hand low down to control the circulation, while Dr. C. R. Byars turned out the placenta and child. With my right hand I held the walls in apposition, to control the hemorrhage. The child being disposed of, pads of hot gauze were placed in the cavity of the uterus, until thorough contraction had occurred. I held the walls of the uterus in apposition, while my son sutured them with eight or nine interrupted sutures, with only moderate tension. After tying the sutures normal hemorrhage occurred only through the vagina. The uterus was then dropped back into the abdominal cavity, and one gallon of warm decinormal salt solution was poured in, the cavity being flushed out thoroughly until the water became clear. Then one and one-half pints of the same solution were poured into the cavity and allowed to remain. In the line of incision of the uterus aristol was dusted, and also along the whole line of incision of the abdominal wound. The latter was closed by through-and-through interrupted silk sutures with only tension enough to coapt the parts well. Towels wrung out of carbolized water were placed over the abdomen to absorb oozing from the stitch holes. After removal of the towels aristol was again dusted along the line of incision, which was then covered with ten-per-cent. iodoform gauze, cotton batting, and a towel to cover the whole. Strips of adhesive plaster, with tape attached, were applied to the skin, and the tapes tied across the dressing, which would enable me to remove the dressing by untying the tapes, and the patient was put to bed. The time consumed in the operation, from the first incision until the abdominal wound was closed, was fifty minutes. The temperature, as a result of the operation, was at no time higher than 100.75° F. Twenty-four hours succeeding the operation, I prescribed sulphate of magnesium and phosphate of sodium, in small doses, to be given every three hours. Although the peristaltic movements of the bowels were very active, and prevented intestinal adhesion which I had feared, still the bowels did not move until the third day, though I had given but little morphine. This inactivity of the bowels was caused by spasm of the sphincter muscles of the anus, which was overcome by dilatation, passing of a rectal tube, and high enemas. The abdominal wound was dressed the first time on the sixth day. There was no pus, and the wound united by first intention all along the line. The sutures were removed on the fourteenth day. No other dressing was required except support for the abdomen. The patient was able to sit up in a chair on the sixteenth day. On the twenty-first day she had an interview with her sister, who disclosed to her the true facts, which caused great prostration, as I had never told her, neither had I permitted any one else to tell her, the results of the operation. Ten hours after the interview she had a severe rigor, and phlegmasia alba dolens in the right leg set in. The temperature rose to 102° and 104° F., for four or five days. The limb was never swollen a great deal. The phlegmasia confined her to her bed for about fifteen days, but disappeared about the twentieth day. The patient has not been discharged up to this time, and is still under treatment for intermittent malarial fever, from which she suffered before the operation and during recovery. In making my diagnosis, I excluded pregnancy as an impossibility, on account of the social standing of the patient, and my personal knowledge of her. The elastic spongy feel of what I thought to be a tumor was after the operation explained by the large size of the placenta, which occupied the whole of the anterior and superior surface of the uterus, the child lying low down in its posterior portion. In conclusion, I beg to state that neither Dr. J. H. Bowers nor Dr. C. R. Byars examined the patient, and did not influence me in making my diagnosis. The child at the time of delivery was about seven and one-half or eight months, and is now enjoying perfect health.

## ANOMALOUS PUPILLARY REACTION IN MENINGITIS.

By ALBERT SEITZ, M.D.,
M'MINNVILLE, TENN.

The following case is one of abnormal behavior of the pupils of both eyes during meningitis in a boy nine years old. I was called in consultation with the attending physician to see the child on May 20, 1899. This physician said he had been treating the patient for about a month for some trouble of the hip joint. On examination I found the boy had tuberculous meningitis, evidently secondary to the hip-joint disease, which was tuberculous. The anomaly in this case was that the patient's pupils contracted to the size of a pinhead in the dark, and dilated widely in the light. The brighter the light, the more quickly and widely they would dilate. I called the attention of the boy's father to this (he having practised medicine several years in early life). I also called the attention of the attending physician to the anomaly, he not having noticed it before. I saw the case again a few days later, just a day or two before the death of the patient, when the same phenomenon was still present. I have never seen this action of the pupils save in this case, and have not satisfied myself as to its cause and *modus operandi*.

## A FEW RARE DOUBLE DISLOCATIONS.

By W. M. JAMES, M.D.,
UTICA, N. Y.

In the fall of 1871, Whitestown Seminary of Whitesboro, Oneida County, N. Y., was in its glory, and its students were numbered by the hundreds. Back of the boarding-house were a few large elm-trees. Attached to a large limb nearly at right angles to the trunk, about forty feet from the ground, were two heavy ropes, the proper distance apart for swinging. Two large iron rings, covered with leather, were secured to the lower ends for grasping with the hands.

Leslie W. Kellogg, a Utica lad of about sixteen years, a student, was much pleased with the swing. When nearly at its full height he lost his grasp on the rings and fell upon the palmar surface of both hands and dislocated both wrists upward. In a short time under chloroform I reduced and dressed the dislocations, and very soon his recovery was perfect. A few days since he reported that he has never known any difficulty from the injury.

On September 2, 1881, Gilbert Smith, of Utica, lived near the lunatic asylum on the main road to Whitesboro. On that afternoon there was a furious thunder shower with much rain. The old house was surrounded by a rickety board fence, the boards being upright and eight feet high. The long service of the fence lessened its safety for acrobatic purposes. Desirous of knowing the damage by the water in a ditch close to the outside of the fence, Smith clambered up on it for a fair view. Very soon he landed across the

ditch upon both elbows, dislocating both shoulders upward and backward. In a short time, while he sat in a chair, I reduced the luxations by manipulations without anæsthesia. He soon had perfect use of the joints and never any further trouble.

On March 30, 1894, a tall, stoop-shouldered German, twenty-two years of age, was brought to my office by his physician. Soon his shoulders were bared, and when about ten feet away I was asked the nature of the difficulty, and reported a double dislocation of the shoulders. On February 13, 1894, while running in soft snow about a foot deep, he fell upon his elbows, causing the accident. The first medical attendant treated him about three weeks with electricity, washes, and other local means for a supposed marasmus. Another had the care of him about the same length of time with no better results. He had consulted three physicians before I saw him. In about ten minutes the dislocations, under chloroform, were reduced, dressed, and he left my office. The subsequent care of the case fell to me, and in less than four weeks he was at work. This young man had quite an experience later. On January 23, 1897, he fell, dislocating the right shoulder. In less than four weeks he was at work again. On April 8, 1897, the same accident befell the same shoulder. On October 2, 1898, January 8, 1899, and March 25, 1899, he dislocated the right shoulder by falling three times more. At each accident I had the care of him. The luxation was reduced by manipulation without chloroform sometimes, and at other times chloroform was given to reduce it. In every case in less than four weeks he was at work and all right. He is now in good health, has good use of his arms, and says he does not feel anxious to have a repetition of the difficulty.

166 Genesee Street.

## REMOVAL OF A FOREIGN BODY FROM THE NOSE.

By D. S. HUMPHREYS, M.D.,

GREENWOOD, MISS.

I was called some time ago to remove a cotton seed from the nostril of a three-year-old child, which I did very easily and quickly by the following method: The nose-piece of an ordinary Politzer's air-bag was inserted into the nostril on the side opposite to the offending substance and the bag suddenly compressed, when out half-way across the floor flew the cotton seed.

It is an ideal method, as the screaming of the frightened child closes the posterior nares and forces the air back through the other nostril.

## A SUPERNUMERARY PLACENTAL CORD.

By ALBERT SEITZ, M.D.,

M'MINNVILLE, TENN.

Mrs. D——, an American woman, white, aged thirty years, weight one hundred and thirty pounds, was married one year before confinement; the family history is good, there are no bad hereditary tendencies, both parents are living and healthy, the health of the brothers and sisters is good, and the personal history is good. This was her first child, with no previous miscarriages, and she gave no history or evidence of syphilis, gonorrhœa, or injury of any kind. All the organs and systems of the body seemed healthy and in good condition, each performing its function properly.

Labor began a little before midnight on May 9, 1899, when I was called. It continued normally until 9 A.M., May 10th, when a female child weighing seven and one-half pounds was born. The presentation was by the vertex, position L. O. A. The whole process of delivery was normal. I handed the child to the nurse after having ligated and cut the cord, and, turning to the mother, placed my hand over her pubic region to ascertain if the uterus was contracting properly, when I was surprised to find the fundus uteri out of its accustomed place. I at once introduced my hand into the vagina, where I encountered the placenta low down, and pushing my fingers on up to the cervix, I found the fundus uteri coming through the neck. I could feel a cord extending from the placenta and firmly attached at the other end to the fundus uteri. I supposed at first that this cord was simply adherent membranes, as I had found this condition a number of times before, but I soon realized that it was too firm and resisting for that. I separated it as quickly as I could from the uterus with my fingers, which was rather difficult to do, and replaced the inverting fundus to its proper location. I then removed the placenta and membranes to which this second cord was attached. I placed the edges of the membranes, where they had been ruptured, in apposition, to see if any had been torn away, and found them all there. I then examined the abnormal development by which the placenta had been attached to the fundus, and found that it was composed of enlarged blood-vessels, both arteries and veins, together with a greatly thickened outgrowth of the membranes, and a substance which exactly resembled the jelly of Wharton. This cord was about five inches long, as large in diameter as the normal cord, had two permanent twists in it, and resembled a normal umbilical cord in every particular except in length. It was attached to the margin of the placenta and to the membranes at this place, and must have been an effort on the part of nature to form a second umbilical cord, the cord proper being in its usual place and normal in every way, as were also the placenta and its membranes, with the exception of this second attempt at a cord. There was no evidence in this case of there having existed a twin pregnancy, nor of the presence of a second or rudimentary placenta, this short cord being attached directly and intimately to the fundus uteri. It was the weight of the placenta pulling on this cord which was inverting the uterus. The mother passed through a normal puerperium, and she and the child are well.

## A PECULIAR CASE OF PERNICIOUS MALARIAL INFECTION.

By BASIL M. TAYLOR, M.D.,

GREENSBURG, KY.

On the evening of November 4, 1896, I was asked to see in consultation a child who was thought to be ill with "brain fever." I saw the case about 8 P.M. The patient was a large boy twelve years old. The following history was given me: This boy came home from school Monday afternoon, November 2d, and was seemingly well. His mother sent him out in town a short distance to a shop. The boy returned in about one hour without having been to the shop, but had wandered around town. He could remember nothing, and was in a state of wild delirium. He was put to bed, and the family physician summoned. He found him in a stupor, with a temperature of 97° F., pulse 72, and respiration 12. There was no vomiting. The patient made no attempt to talk or move. He was given a purgative and cold was applied to his head. He was thought to have congestion of the brain. His condition did not change, and he did not swallow anything on Tuesday or Wednesday.

I found him Wednesday evening in a complete stupor. Temperature, 96° F.; pulse, 68; respiration,

12, and very shallow. The pupils were not contracted, but reacted sluggishly. I could find no symptoms of brain trouble, and, suspecting pernicious malarial fever, I obtained a drop of blood for examination. A microscopical examination revealed the presence of malarial plasmodia. I explained to the physician the nature of the disease, but my diagnosis was not accepted, and the cold pack for "brain fever" was kept up. There was no change in the patient's condition.

On Friday November 7th (the fifth day of the disease), I was asked to take charge of the case. The temperature was then 96° F.; pulse, 65; respiration, 12, and shallow. The patient was still in a profound stupor, his urine being passed involuntarily. The patient had swallowed nothing since Monday. There was no vomiting. The skin was cool and dry.

I gave him hypodermically gr. xx. of quinine every three hours—beginning Friday afternoon at three o'clock. On Saturday at noon his temperature was 98.5° F.; pulse, 76; respiration, 16. His mind was clear, and he was able to swallow a little water. He remembered nothing that had happened since he left school on Monday. The quinine was given in gr. v. doses every three hours for several days. An examination was then made and showed an absence of plasmodia. The patient made a complete recovery and has had no return of malarial symptoms.

This case is peculiar on account of its severity and the duration of the disease before any relief was obtained, and gratifying on account of the quick response to the treatment—which was, I must confess, a little akin to heroic.

## A CASE OF LYMPHOSARCOMA OF THE NECK.

By S. S. WILLIS, M.D.,

AND

V. F. MARSHALL, B.S., M.D.,

APPLETON, WIS.

A SARCOMA may be defined according to Senn as "an atypical proliferation of connective-tissue cells from a matrix of fibroblasts of congenital or post-natal origin." Cohnheim defines sarcoma as "an atypical new formation starting in a latent embryonic rudiment."

Lymphosarcoma or primary sarcoma of the lymphatic glands of the neck is comparatively a rare affection. Dennis has recorded but two cases. The histological examination of a lymphosarcoma reveals that it is made up usually of small round cells surrounded by a delicate network of fibres; occasionally spindle cells may be present. Usually the characteristic distinction of this form of tumor is that the cells do not limit the vascular spaces, nor is the blood supply as prominent as in the other varieties of sarcoma. The tumor is disseminated through the surrounding glands, and thus becomes a source of general infection through the lymph stream. Heredity may be found at times as an etiological factor. Children and young adults are subject to the disease, though glandular sarcoma is not uncommon in those of more advanced age. Traumatism plays an important rôle in the causation of this form of tumor.

The symptoms of lymphosarcoma are not pronounced unless a nerve or nerves are involved in the growth or have been pressed upon by the tumor. The tumor appears at first without any pain or discomfort to the patient. In its advanced stages, metastasis occurs, and after the disintegration of the tumor the patient becomes weak and emaciated, losing flesh and strength rapidly. Lymphosarcoma is to be diagnosticated from tuberculous glands, syphilis, carcinoma, leukæmia, and pseudo-leukæmia or Hodgkin's disease. Tuberculous glands do not attain a large size so rapidly as does sarcoma, and there are always present other constitutional symptoms. Carcinoma does not grow so rapidly, usually occurs in people of advanced age, and the tumor is not globular; it is usually attached to the skin overlying it, and tends to ulceration earlier than sarcoma. In syphilis there are the history of infection, a multiplicity of tumors which do not attain the size of sarcoma, and finally, the disease yields to the classical treatment. As regards leukæmia and pseudo-leukæmia, we have in the former the blood-producing organs becoming successively affected and the microscope showing the characteristic changes, while in pseudo-leukæmia other glands become involved. The prognosis of lymphosarcoma is usually favorable when but one gland is affected, and the early removal of the tumor, together with the adjacent infected tissue, is obtained. In the rapidly-growing, soft, and small round-celled lymphosarcoma the prognosis is not favorable, unless an early diagnosis is made and the radical operation is performed. The surgeon should aim to secure union by primary intention, as sarcoma is prone to recur when such union has not been secured, and especially when some of the cellular elements have been left behind. The treatment may be medicinal or surgical—the former conservative, the latter radical, consisting in a complete extirpation of not only the affected gland, but the tissues around it. The toxins of the streptococcus erysipelatosus of Fehleisen have been used in advanced cases with variable results by Coley and others. When there is a multiplicity of tumors and surgical intervention is hopeless, this may be used as a palliative measure. The addition of the toxins of the micrococcus prodigiosus is said to enhance the effect of this procedure. Arsenic, in the form of Fowler's solution, has been used, both internally in large doses and hypodermically, but the results have not been satisfactory. The radical operation—total extirpation of the tumor with the tissue surrounding it—has been the most successful treatment. The following is the history of a case which came to our notice:

Mr. N——, aged forty-six years, was an only child. His mother is sixty-four years of age, and in good health. His father, who was an alcoholic, died of tuberculosis at the age of forty years. He has never had any of the usual diseases of childhood, but suffered from epileptic convulsions until twelve years of age. He uses tobacco and alcohol to excess. He had never consulted a physician until last April, when he came under our observation for a tumor which appeared on the right side of the neck, in the region of the cervical glands. The patient being of light complexion and delicate, anæmic appearance, a blood count was made. The number of red blood corpuscles was found to be 4,485,000, and the white 7,360, with no irregularity or abnormality in color or shape. The patient stated that he had first noticed the tumor about ten days before, but that it had caused no pain or other bad symptoms. Upon examination we found the tumor to be about the size of a walnut, elastic, non-adherent, and originating from one of the cervical glands. There was no history of trauma or syphilis. The patient was placed upon iodides and iron, and told to return at the expiration of one week. He appeared at our office again after two weeks, and upon examination we found that the tumor had grown very rapidly, and now was about the size of a small orange. It was globular, elastic upon palpation, somewhat movable, and the skin non-adherent. The tumor was overlying the large cervical vessels and under the sternocleidomastoid muscle, which was pushed anteriorly. Believing the tumor to be a lymphosarcoma, we advised operation. After a lapse of two weeks he again appeared at the office, stating that it was causing some pain and discomfort, and that he would now consent

to the operation. The tumor had now attained the size of a large orange. He was operated upon under chloroform anæsthesia, six weeks only having elapsed since the tumor was first noticed. The operation was done as follows: A linear incision was made along the line of the cervical vessels, extending from below the mastoid process to about two inches above the clavicle. The tumor was soft and elastic, no vessels penetrating it. A portion of the sterno-mastoid muscle which was adherent was removed. Several of the superficial cervical nerves were sacrificed, as they penetrated the tumor and no doubt gave rise to the pain the man had experienced previous to the operation. The large cervical vessels were exposed, but the spinal accessory nerve was not sacrificed. The tumor was now found to involve the deep tissues of the neck, which necessitated a deep and tedious dissection. The cervical plexus, which was plainly visible below, was not injured by the removal of the tumor. As much of the surrounding tissue as possible was dissected out. The wound was closed in the usual way, a small amount of gauze drainage being inserted at the lower angle, and removed two days later. The wound healed by primary union, and the patient was discharged on the tenth day.

Macroscopically the tumor was about the size of an orange. On section the middle portion was soft and of light color, friable, and evidently undergoing fatty degeneration. The microscope confirmed this opinion, and proved the tumor to be a lymphosarcoma made up of small round and spindle-shaped cells, and a small amount of fibrous tissue.

782 College Avenue.

## POISONING BY ALCOHOL, CHLORAL, AND POTASSIUM BROMIDE.

By NORMAN P. GEIS, M.D.,

BROOKLYN, N. Y.

Mrs. A. C——, forty-three years old, widow, on Friday, being troubled with headaches and sleeplessness for several nights, went to a physician and was given a prescription containing several drugs and was told to take a teaspoonful at 9 and 10 P.M. At 9 P.M. she started to take the medicine and continued to take it at short intervals until 3 P.M. Sunday. In the course of forty-two hours she took six ounces of the mixture, which contained 720 grains each of chloral and potassium bromide, in addition to other ingredients. Also during the same time she took three quarts of whiskey and one quart of wine. She was given other whiskey besides this, but the amount of which I do not know. Probably it was not more than six or eight ounces. She was semi-conscious off and on during Saturday and Sunday, and was often very violent. I first saw her at 9:30 P.M. Sunday, no other doctor having seen her since Friday. She was in bed in a stupor, with face and lips extremely blue, and panting for breath; the skin was hot; the pupils were widely dilated and equal, but would contract down to a pin-point and then as suddenly dilate again. The heart was irregular, intermittent, and extremely weak in its action, the pulse being 150 to the minute. The bowels had been moving involuntarily since Saturday. She could be roused and would speak, but not connectedly. She denied having taken anything, but was four days behind in her time, believing it to be the 16th when it was the 20th of the month.

I was able to bring her out of the stupor with strychnine sulphate and pilocarpine hydrochlorate in three hours. That night I tied her down in bed so as to prevent her doing herself or any one else injury, as she became violent at times. On Monday she was greatly improved, although extremely weak. Her heart was reacting slowly and her pupils dilated and contracted the same as before. In the afternoon, against my orders, she got out of bed, dressed herself, and went downstairs. A slow recovery took place.

I think recovery in this case is remarkable. According to Potter, 30 grains of chloral has proved fatal, but then again as much as an ounce has been taken, although not in one dose. Potter says that a single dose of 200 grains has been taken without a fatal termination. Hammond reports a case in which 75 grains of potassium bromide was taken every day for ten days when death resulted. My patient took 720 grains in forty-two hours against 750 grains in ten days. As is known, the action of chloral is increased by the addition of potassium bromide and vice versa, and therefore the poisonous effects of both were increased. The great amount of whiskey taken would also cause depression on the already weary heart, but in this case it must have stimulated and kept the patient alive, for otherwise she must certainly have died.

## ACUTE ALCOHOLISM WITH CONVULSIONS.

By JOSEPH G. WILSON, M.D.,

MT. PLEASANT, OHIO,

LATE ACTING ASSISTANT SURGEON, U. S. ARMY.

During the late war it fell to my lot to see a number of these cases among our soldiers in Porto Rico. The following cases are fairly illustrative:

Case I.—W. G——, private, aged twenty-two years, drank a large quantity of native rum during the morning and afternoon of November 15, 1898. During the afternoon the combative nature of an ordinary drunk began to assert itself. At 4 P.M. he was seized with violent pain in the belly, the muscles of the abdomen being severely cramped. Spasms of the voluntary muscles now began to show themselves—complete opisthotonos being assumed. The convulsions were similar to those of strychnine poisoning, there being complete relaxation between the attacks. In the intervals the severe mental symptoms of a man crazed by drink manifested themselves—two or three men being necessary to control the patient. The treatment consisted in the administration of gr. $\frac{1}{8}$ apomorphine hypodermatically. In three minutes there was copious emesis of large quantities of unmasticated food. The patient then grew quiet and slept till 7 P.M., when similar convulsive motions manifested themselves. A catheter was passed and from twelve to thirteen ounces of urine were drawn off. On the morning of the 16th the patient was still in a somewhat dazed mental condition, and had a recurrence of slight convulsive movements. On the 17th he was discharged.

Case II.—H. A——, private, aged twenty-three years. He drank five glasses of native wine, followed by one drink of Canadian Club whiskey. He was shortly seized with severe abdominal pain and violent convulsions, opisthotonos being complete. During the intervals free from convulsion he manifested marked combative tendencies. Treatment consisted in the administration of gr. $\frac{1}{8}$ apomorphine hypodermatically. The man vomited in three minutes, and immediate relief followed with a perfect clearing of the mental condition, which had before been that of a man dazed and crazed by drink. He was discharged the next day. Neither of these men had been frequent indulgers in alcohol. They both were affected in a precisely similar manner upon subsequent occasions when they again partook of native drinks to excess. The first man seemed to become gradually immune, and his attacks became less alarming in character. The second man was so alarmed at his

third attack that he forswore the poison and confined himself to beer. Conclusions from these and other similar cases would seem to indicate: (1) Acute alcoholism with convulsions is more common among those who only occasionally indulge to excess; (2) the more crude and unrefined the drink the more likely is the attack to occur; (3) prompt emesis is the remedy *par excellence*.

## RELAPSE IN MEASLES.

By THOMAS W. HARVEY, M.D.,
ORANGE, N. J.

The following case of relapse in measles is unusual enough to be recorded. In an epidemic at the Orange Orphan Home, where we had forty-six cases, one of the children, Margaret Jones, aged eleven months, was taken with the usual symptoms of measles, and the eruption was well broken out on June 10th. She had the catarrhal symptoms well marked, and the temperature during the first four days varied between 101° and 103.2° F. There was a bronchitis of moderate severity. The rash was gone at the end of the first week, and after a slight desquamation the child was returned to the nursery as convalescent on the eighteenth day. Two days later the child was found to be ailing again; she had coryza, inflamed eyes, and a slight rash on the face. On the next day the temperature ran up to 103.6° F.; by the next day the rash was typical and universal, and for three days the temperature remained above 105° F. The child had marked bronchitis and gastro-enteritis. A profuse desquamation began soon and continued for the next ten days, all the other symptoms in the mean time steadily improving, and on July 17th the child was returned to the nursery again as convalescent.

Systemic writers make little or no mention of relapses in measles; but as an example of coincidence of these rare cases, I may say that on the day I recognized that I had met this condition for the first time my attention was called to an article in the *Medical News*, in which two cases were reported.

## ECTOPIC PREGNANCY.

By H. R. LANKFORD WORRALL, M.D.,
BUSREH, ARABIA.

On a recent tour to the Arabian mainland at a place called Katif I was called to see the following case: A. B——, aged about twenty-five years (Arabs cannot tell their ages), primipara. She was said to have become pregnant over two years ago. The motions of the child were felt about the fifth month, but all motions ceased about the seventh month. At the ninth month delivery was expected, but there were no pains. Last year she had a discharge of pus from the umbilicus. A few days later, perhaps a month, the bones of a hand and an arm presented and were extracted (pulled out) through that opening. Which arm it was that came out was not remembered. Later all the body except the head was discharged. The woman has lately been very weak. There had been no special discharge from the vagina since impregnation save a little blood and watery fluid, but nothing like the menses. The temperature was 101° F., pulse 130 at the time of my visit. The woman was small, thin, and much wasted: the tongue was slightly coated. Headaches occurred sometimes, but usually the patient felt well. There was a discharging sinus at the umbilicus. The abdomen was only slightly enlarged. On palpation, two globular masses were found over the pubes. One was hard and easily recognizable as a fœtal head, the other was similar to a slightly relaxed uterus after childbirth and was of the size of a small teacup. Slight pressure over both ovaries gave intense pain—in fact, the entire examination gave pain. The spleen was enlarged, but not unusually so for this part of the world. The liver was apparently normal. The kidneys were acting normally, the bladder was not distended, the bowels were constipated, but no fecal accumulations were recognizable.

Vaginal examination was refused. From the physical signs only ectopic pregnancy was diagnosed. The following questions arose concerning the condition presented: (1) Are there any cases recorded of ectopic pregnancy being relieved naturally through an external opening? (2) Although the head was at the time of examination outside, above, and slightly to the right of the uterus, could the condition have been originally any other than ectopic pregnancy?

# Society Reports.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

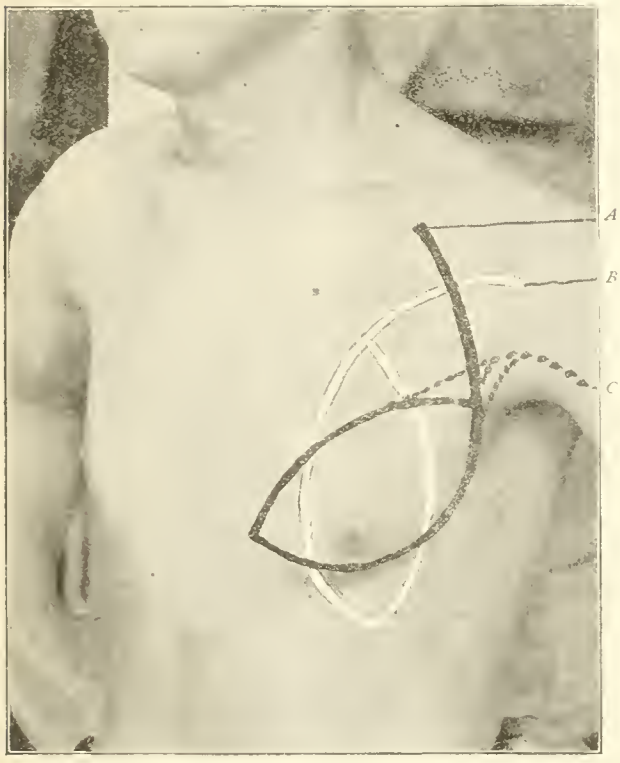
*One Hundred and Forty-Ninth Regular Meeting, Held on Friday, October 13, 1899.*

Dr. A. Alexander Smith, President, in the Chair.

**Resection for Double Ankylosis of the Jaw.**—Dr. Robert F. Weir presented a lad, aged fourteen years, who had been crippled in various joints during the past six years by rheumatoid arthritis. Among the joints affected were those of the jaw. During the past two years the teeth had been forced apart several times quite widely, but the contraction had recurred. On June 1st of this year, when Dr. Weir had operated, there was complete immobility at both sides. The operation done was that of Humphrey, modified by Kocher. The line of incision was a short, oblique one, across the posterior part of the zygoma, the lower part anterior to the temporal artery and with the anterior end of the cut running a little upward, but here only through the skin, to give additional operative space. By cutting or tearing through the attachment of the masseter, the head and neck of the bone were quite easily exposed, divided with a chisel, and the fragment, three-fourths of an inch long, with the fibrously ankylosed head, wrenched out of place. Temporary plugging checked all bleeding. A small drain was left in the wound, which was otherwise closed with sutures. Prompt union occurred, and early motion was secured by the use of chewing-gum and the frequent insertion of wedge-shaped pieces of soft vulcanized rubber. The patient could now distend his mouth widely, and was without any impairment to the orbicular muscles of the eyes.

**Amputation of the Breast by Kocher's Method.**—Dr. Weir also showed a patient from whom, in March, 1898, he had removed a carcinomatous mamma of six months' duration by the method of Kocher. The incision was the point to which he directed attention. Instead of running ovally around the breast and then to the axilla, or, better still, above its anterior border, where it was usually curved downward a little on the arm, Kocher cut from the outer end of the oblique oval, circumferential breast incision almost directly upward, or with a slight curve bowing outward, to just beyond the middle of the clavicle. Through this cut he immediately divided the pectoralis major and minor, opened the axilla, freed the vessels and nerves, and removed the axillary contents to the clavicle. Then forward toward the median line, the affected mamma with the pectoralis was dissected off and removed. Dr. Weir said he was not satisfied with the

usual Halsted incision, because not infrequently he had seen it followed by decided sloughing at the point of its long axillary flap. He preferred the incision used for many years, namely, that extending from the breast to the arm just above the anterior axillary border, with its downward curve if more room was required, or for treatment of humeral gland involvement (see diagram). The result in four cases done by the Kocher method was good, although the procedure was a little more difficult than the other one. Neither of



*A*, Kocher. *B*, Halsted. *C*, Hartley.

these methods was followed by any impairment of the arm function, and Dr. Weir said that since adopting the advance inaugurated by Heidenhain and Stiles in 1892 his percentage of cures, *i.e.*, non-recurrence after three years, had advanced from twenty-two per cent. to forty-two per cent.

**Removal of a Large Gouty Tophus.**—Dr. Weir also reported the details of a case of a very large gouty deposit on the foot of a man aged fifty years, which measured three inches across, projecting an inch and a half above the great-toe joint, and spreading outward to the fourth toe of the right foot. On account of its size a specially made shoe was required, and from an ill-fitting one inflammation and suppuration had ensued. Free incisions and prolonged scrapings were required in order to remove the accumulation of urate of sodium. A good deal of this, of necessity, remained behind, and hence the repair was somewhat slow and final healing was considerably delayed. It involved and probably originated about the metatarsophalangeal articulation of the great toe.

**An Instructive Case of Appendicitis.**—Dr. Andrew H. Smith reported the following: At Elberon, N. J., on Saturday evening, September 2d, I was called to see Mr. L——, aged seventy-three years, an exceptionally healthy and vigorous man for his age. He was sitting with his family, and complained only of colicky pains, which he attributed to indigestion from imprudence in diet. His tongue was slightly coated, but he stated that his appetite was unimpaired. His pulse was 72, and his mouth temperature 98.6° F. On my inquiring as to tenderness he punched his abdomen vigorously with negative result. I afterward learned that he had had more or less "indigestion" for several days, but he did not give any prominence to this at the time. Under the circumstances I did not submit him to a physical examination as I should have done, but simply ordered a mercurial purge to be followed in the morning by a saline water. The next morning I found him much relieved, the bowels having acted freely. He had taken his breakfast with his family, and had enjoyed it. In the afternoon he sent for a "prescription for a pain in the bottom of the stomach," the bowels continuing to move. He was about the grounds, and sent word that it was not necessary that I should call. I gave the messenger a prescription for paregoric and spirits of chloroform. At seven o'clock the next morning (Monday) he sent a carriage for me. I found him in bed, and very much alarmed by the discovery of a "lump in his stomach." The abdominal wall being thin and perfectly flaccid, the tumor was immediately apparent to the touch. It was clearly defined, movable, hard, elongated, irregular, and knobby in form, and about the size of the last two joints of my middle finger. It lay a finger's breadth external to McBurney's point, and seemed to be covered by scarcely half an inch of tissue. It appeared as if with a touch of the knife it would present immediately in the wound. It was but slightly sensitive to pressure. But for its hardness and elasticity, it might have been mistaken for an isolated mass of fecal matter. The temperature was absolutely normal, and the pulse was 72. The consent of the patient to an operation having been obtained, I at once called up Dr. Abbe on the telephone, and dilated to him on the exceedingly pretty operation which he had in prospect. It was arranged that he should take a train leaving New York at eleven o'clock, and arriving at a little before one. At half-past eleven, when Dr. Abbe was already on the way, the patient, while rising on his elbow to sign a paper, was seized by a sudden and excruciating pain in the region of the tumor, "as if a knife had been driven into the belly, and was being twisted about among the intestines." Within fifteen minutes I was present, but the condition of the abdomen had completely changed. There was a considerable degree of tympanites, the abdominal muscles were rigid and tense, and the entire right iliac region was exquisitely tender. The tumor could no longer be felt. A quarter of a grain of morphine under the skin controlled the pain, and by one o'clock the patient was on the table. The pulse was then 100, and the temperature was 101° F. On opening the peritoneum it was seen that there had been an escape of pus, which had flowed down into the pelvis, there being no limiting adhesions. The appendix was found deep down in the iliac fossa. It was gangrenous at the base, and there was an opening into the caput coli at the point of junction. My own opinion was that the tumor, which was so palpable in the morning, consisted of a small abscess with very tense walls, which was situated upon the anterior and inner aspect of the caput coli at the base of the appendix, and which subsequently burst into the peritoneal cavity. It is true that nothing corresponding to the wall of such an abscess was discovered, but it is equally true that the appendix itself did not present the appearance of having contained more than a few drops of pus, and that no other pus cavity was encountered. Moreover, the location of the appendix was not that of the previous tumor. A second incision was made in the median line, and the pus in the pelvis carefully sponged away. Both wounds were packed with gauze, and the patient made an uneventful recovery.

Dr. Smith also contributed a short paper on "Diagnosis of Obliteration of the Receptaculum Chyli" (see page 813).

**Chronic Stiffness of Spinal Column.**—Dr. C. L. Dana reported two cases of chronic stiffness of the spinal column and one of spondylosis rhizomelia, and referred to the attention that was being given to these conditions by a number of French and German neurologists. Several years ago a Russian neurologist (Bechterew) described a form of chronic stiffness of the spinal column, which he thought had some unique clinical characteristics. The cases occurred in middle-aged or elderly people; generally men, and were characterized by a gradual and progressive rigidity of the spinal column without involvement of the joints of the limbs. The disease was accompanied with some pain, especially around the chest; with feelings of constriction, and of various prickling and numb sensations. There was some wasting of the muscles of the trunk, and a gradual bending forward, or kyphosis. Eventually the respiration became almost entirely abdominal, and the patients were held in a rigid, bowed condition. Bechterew reported one case, with autopsy, in which he found a chronic meningitis involving the pia mater; the roots of the spinal nerves and to a slight extent the spinal cord were also affected. The vertebral bodies showed atrophy with loss of the intervertebral discs, and this, together with the muscular atrophy, explained the kyphosis. The disease was a very chronic one, but usually did not end fatally. It was caused, apparently in some cases, by traumatism, and in some cases simply by a hereditary tendency to extreme round shoulders. In one case, that in which there was an autopsy, there was a history of syphilis. Bechterew had described these cases clinically, without being able to express a positive opinion as to their pathology in all cases. He recorded some other cases which had been reported, and which had generally been classed under "rheumatoid arthritis." Bechterew referred to his cases as "chronic stiffness of the spinal column." Dr. Dana stated that about a year ago Dr. P. Marie had reported two cases of a form of chronic stiffness of the spinal column, which he called "spondylosis rhizomelia," the term meaning a morbid condition of the vertebral column and of the large joints; that is to say, the hips and shoulders. Marie had referred to the fact that Strümpell had noticed this disease, and had given a short description of it in his "Text-Book of Medicine." In Marie's cases the disease also affected only men, and attacked them during middle life or after. It usually began in the hip joints, causing a progressive ankylosis of these joints, then extended upward, and involved the back and the shoulder joints, but did not involve the smaller joints or the limbs; occasionally, however, one or both knees were involved. This trouble was also a slowly progressive one with some pain, but without any swelling or evidences of inflammation. The back became gradually more and more curved and rigid, though this curvature was not always present. In these cases there was absence of the constricting feelings and paræsthesias found in Bechterew's cases; here, too, the disease was very chronic, and treatment would only alleviate the symptoms. Discussing the pathology of these two forms of chronic spinal stiffness, Dr. Dana said he thought most of the cases described and referred to by Bechterew were secondary forms of spinal rigidity, due in some cases to a chronic meningitis or syphilis, while perhaps in other cases they were unusual types of rheumatoid arthritis. He referred to the fact that gonorrhœal rheumatism would sometimes lead to a chronic stiffness of the spinal column. He considered that the cases of Marie termed "spondylosis rhizomelia" were probably forms of rheumatoid arthritis. This disease developed in two ways: a peripheral form, which began in the small joints, and occurred usually in early life, affecting women more than men; and a central or senile type, which began in the back or hips and gradually extended peripherally. It seemed to him probable, therefore, that the Marie type of disease was only an example of the central or senile type of rheumatoid arthritis. The speaker also described and showed some illustrations of chronic stiffness of the spinal cord, described by Marie in conjunction with Astie. This type was considered to be due partly to hereditary predisposition and partly to trauma, and was called by Marie and Astie the "hereditary traumatic type of stiff spine."

Dr. Walter B. James said that during the past eighteen months he had had under his observation a case which bore some similarity to the condition described by Dr. Dana. The patient was a man thirty-five years old. During the past two or three years he had noticed that his thoracic spine was gradually becoming stiff and arched, although the deformity, thus far, was not sufficiently marked to be noticable when he had his clothes on. The upper part of his body was not so pliable as it should be, his motions in turning around were sluggish, and his gait was rather shuffling. In addition to this, he was suffering from symptoms which were supposed to be due to intestinal indigestion. He was constipated, had a coated tongue, and suffered from periodical attacks of marked mental depression; at such times he was more or less hypochondriacal. His urine contained large quantities of indican and oxalate of lime. Dr. James said that he had been inclined to regard the case as a trophic neurosis, closely resembling rheumatoid arthritis, but limited to the spine. It was first regarded as a case of Pott's disease, and several orthopedic surgeons told him that he would be humpbacked within a year. The progress of the spinal curvature, however, had been so slow as to be almost imperceptible.

Dr. Andrew H. Smith asked if there had been any post-mortem examinations made with the idea of ascertaining the condition of the vertebræ. He thought that such a sharp curvature of the spine was hardly consistent with integrity of the bodies of the vertebræ.

Dr. Dana replied that a post-mortem was made in one of Bechterew's cases, and revealed atrophy of the intervertebral discs with some atrophy of the bone, but no inflammatory osteitis.

Dr. Beverley Robinson asked if the hip joints remained unaffected in most of the cases. In a case of this character which had been under his observation at St. Luke's Hospital last spring, in which the trouble had existed about eighteen months, the vertebral column and both hip joints were affected.

Dr. Dana said that in the senile type, of which he had reported an instance, the hip joints were not affected, but in the other type the trouble usually began in the hip.

Dr. W. Gilman Thompson said he entirely agreed with Dr. Dana that the case represented a variety of arthritis deformans with a peculiar localization, the disease not affecting the smaller joints as it usually did.

Dr. Dana, in closing, said that one class of cases to which he had referred in his paper probably represented a type of arthritis deformans, but on account of their peculiarity they seemed to deserve a special class by themselves: the other type, of which he had reported an instance, and to which type the case referred to by Dr. James apparently belonged, had a pathology which must still be worked out. In one of Bechterew's cases, the post-mortem showed conclusively that the morbid condition was not that met with in arthritis deformans.

---

**In Formaldehyde Disinfection** the disagreeable odor can be removed, it is said, by sprinkling the floor with ammonia water.

# Correspondence.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE WAR AND THE ARMY MEDICAL STAFF—COLLEGE OF SURGEONS; PROPOSED CHARTER AND GOWN—ANTISTREPTOCOCCUS SERUM—DEFENSE SOCIETIES—DEATHS OF DRS. ARNISON AND ARLIDGE.

LONDON, November 10, 1899.

THE leading topic everywhere is, of course, the war, and its medical aspects are not so encouraging as many expected. The flouting of army surgeons by the late and present commanders-in-chief has done its evil work, and the bad example is followed by Buller and others. The medical department is undermanned; even the service papers are saying so. It is no new thing for hospital surgeons to go to the seat of war. They went to the Crimea. But the War Office seems to seek only a means of dazzling the public by showing concern for the wounded. They would have done better to have kept up the strength of the R. A. medical corps, which is now twenty per cent. lower than it was thirty years ago, and that notwithstanding the increase of the army. Hence a number of civil surgeons have to be hastily engaged, and to throw dust in the eyes of the people the War Minister must get some eminent men to go out as consultants. The real need was and is an increase in the strength of the corps. For the need the authorities are entirely to blame. There is plenty of material, but they would not pay for it either in position, leave, or hard cash. There will be a heavy reckoning yet when once the public is aware how the medical department has been starved by the military authorities. The Minister of War in this cabinet has shown some appreciation of the medical staff and some energy in settling the question of titles. Let him now curb the arrogance of the commander-in-chief and show his permanent staff that they must move with the times.

The report of the council of the College of Surgeons has been issued in advance of the annual meeting to be held on Thursday next. The choicest passage tells that last year's meeting passed a resolution against a new charter unless the members were given representation, but the council thought this "inopportune," the sole object of the proposed new charter being to give the council the right to elect honorary fellows. These distinguished people would have no right to take any office in the college or to be registered as practitioners. In fact, they would have no privilege whatever except to put after their signatures F.R.C.S. Eng. (Hon.). It is whispered that the council is envious of its sister college and wants to enroll the Prince of Wales. Meantime the society of members has by no means "inopportunely" submitted to the privy council a temperate statement objecting to the new charter unless representation of members is included.

There was a meeting of the council on the 2d inst., and it was solemnly resolved—what do you suppose? to agree to representation? Not at all. It was resolved that a request of a few members that the council should institute a gown for them to wear be acceded to! A committee is accordingly studying the great clothes question! And the thousands of members are waiting for their rights, while a score or two are being promised a gown!

There seems to be plenty of room for doubt as to the value of antistreptococcic serum, and this is not surprising considering that it has been employed on a hasty hypothesis in a mere empirical manner. Not much is known of the effects of the serum, and still less of the streptococcus itself. Many cases have been reported as successful which, if carefully scrutinized, seem very inconclusive. In more of them other measures were certainly as much entitled to the credit. In some the patients do not appear to have been in much danger. In many the presence of the streptococcus is not asserted. Statistics cannot help us much, and we are thrown back upon the impressions of clinical observers who have used the serum, mostly as remarked above in conjunction with other measures.

The subject was discussed at the last meeting of the Obstetrical Society on the initiative of Dr. Herman, who submitted two cases which got well after the use of serum, although his prognosis was very unfavorable. In one a severe operation was followed by great prostration, from which the patient rallied, but a relapse followed such as in his former experience ended in death. Serum was tried, and the symptoms quickly improved and recovery ensued. The other case was puerperal, and severe rigors on successive days led him to think pyæmia had set in and secondary abscesses might be expected. Serum was tried; the symptoms abated, and there was only a small patch of cellulitis which ended in resolution. Dr. Herman admitted the uncertainty of prognosis, but thought judgment might be helped by such cases.

Dr. Clapham mentioned a case in which, after washing out the uterus with bichloride and later curetting, serum was resorted to, but the temperature, though it fell at first to 102° F., rose again to 105° F., and did so for five nights. Subsequently improvement occurred, though an abscess delayed recovery.

Dr. Horrocks thought in bad cases serum afforded the only chance, though he was less hopeful than in his earlier cases.

Dr. Routh said we could never be sure how much credit was due to serum, as we ought not to omit other measures.

Dr. Cullingworth mentioned cases showing the extreme difficulty of estimating the effects, and said every case should be recorded.

Dr. Eden said the streptococcal origin of puerperal fever was not proved, and the presence or absence of the microbe should be always determined; otherwise the treatment was only empirical. On this Dr. Cullingworth remarked that the first object was to cure the patient, to which Dr. Eden replied that it was not needful for the patient to be kept waiting while the bacteriological examination was being carried out.

Dr. Robinson mentioned a case in which there was a whitish-yellow membrane on the vaginal wall in which streptococci were found. This melted away in a day or two after the use of serum, and the patient began to recover.

Dr. Pollock suggested that cases of pure infection resulted in recovery, and the others were due to mixed infection.

Dr. Maclean said the serum which produced immunity to one germ was perfectly tolerated by others.

Dr. Horrocks said the serum was probably safe if properly sterilized, and might even contribute to nourish the patient; for a dog had been kept alive by injections of serum for three months and did not lose weight. It should not be used if turbid; but a little color did not matter.

Dr. Spencer doubted whether the streptococcus was as frequent as all other organisms put together as a cause of septicæmia. The treatment was purely empirical while the organism was not proved to be present. The injections were not free from danger, as death had occurred soon after them, and they were followed in other cases by a rise instead of a fall of temperature.

The president, Mr. Doran, said however desirable such a remedy might be, he feared that serum could not at present be said to be such.

From the foregoing you will see that the obstetri-

cians have little if any certainty to contribute to the subject. The impressions of careful observers deserve attention, but further investigation of the bacteriology is required, and meantime a little scepticism and more logic might advantageously be cultivated.

The Medical Defence Union has done good work. So has the Protection Society. But two such organizations are not needed, and I have more than once remarked that they ought to amalgamate. The latter has offered to do so, but the Union declined to discuss the suggestion. Surely there should not be any difficulty. In these days when competitors in trade are forming huge combinations, there should be no senseless rivalry between societies formed for such good work as this. Both are weakened by division, for many refrain from joining because they cannot decide which to support.

Dr. William Christopher Arnison, professor of surgery in the University of Durham, died last Saturday at Newcastle-on-Tyne, aged sixty-two years. He was for many years surgeon to the Royal Infirmary and held other offices. He graduated at Durham in 1860, and in 1896 his university gave him a D.C.L. Among his contributions to surgery are some "Cases of Laminectomy" in *The Annals of Surgery*, 1895. Dr. Arnison was able to lecture in the evening of October 30th, though he felt unwell. Later he had great dyspnœa and became collapsed, and he died early in the morning of November 4th, his medical friends having been able to do little for him. Some one hundred and fifty pupils attended the funeral, with representatives of the university, the infirmary, and other public bodies.

Dr. J. T. Arlidge, who died on the 27th ultimo, was the author of the standard work on "The Hygiene, Diseases, and Mortality of Occupations." This valuable contribution to our knowledge of the subject was founded on his Milroy lectures at the College of Physicians, and appeared in 1892. The next year he was appointed a member of the royal commission to inquire into the condition of work-people in the potteries. This resulted in the recent regulations which have already improved the sanitary state of the factories of the district. It must have been a great satisfaction to him to know that his labors had been fruitful. He was the author of many other contributions to our literature, and at one time edited the *Medico-Chirurgical Review*, a quarterly which was discontinued some years ago. The day of quarterlies seems to have passed by. Dr. Arlidge was a graduate in arts as well as medicine of the London University. In 1869 he was elected a fellow of the College of Physicians, by which time he had attained an enviable position as a provincial physician. He was the senior magistrate of the borough of Newcastle-under-Lyme, where he resided for some thirty-seven years. About eighteen months ago he was seized with paralysis, and died on the 27th, aged seventy-seven years.

**Professor Atkinson, the Bone Setter, and the Kaiser.**—Professor Atkinson, the bone setter, who, it will be remembered, plied his trade with remarkable financial success in New York some year or two ago, has lately been interviewed in Great Britain. Among other eulogistic remarks on his own surpassing skill, he asserted that he could give back to his Imperial Majesty, "the German Kaiser," the full use of his left arm. Probably the ability of the learned professor to accomplish this surgical feat will be doubted by a few sceptics, but even if it be possible we implore Professor Atkinson, for the sake of the peace of the world, not to perform this seeming miracle. That is, if the Kaiser will afford him the opportunity. The Emperor of Germany with only one arm has energy enough for a man with four, and the results would be hard to tell if he had the use of two.

## New Instruments.

### A NEW GASTRIC DOUCHE.[1]

BY MAX EINHORN, M.D.,

NEW YORK.

DOUCHING of the interior of the stomach with water under considerable pressure was first applied therapeutically by Malbranc,[2] principally in cases of gastralgia. For this purpose Malbranc employed the ordinary apparatus used for gastric lavage, with the only difference that the funnel was held up quite high. Ewald[3] devised a very large funnel holding about two quarts of water, which when raised still more increased the pressure. In both instances the ordinary stomach tube was used. An improvement in this method of douching the stomach was accomplished by Rosenheim[4] and Boas,[5] who constructed a special tube for this purpose, provided with a great number of very small openings at the end. The apparatus, however, has this drawback, that if the tube is provided with small openings only, the water when admixed with mucus cannot easily return, or will come back without the mucus, which remains in the stomach almost as if it had been filtered. If the tube, on the other hand, has besides the very small openings a large one, the water will, of course, run out principally through the latter, and thus no douching will be effected. The douche described by J. W. Bell[6] acts in the same way. It resembles the Rosenheim douche with the exception that a pumping ball is inserted in the middle. In order to avoid the difficulties mentioned M. Gross[7] and F. B. Turck[8] have constructed gastric douches which are provided with a double-current tube. The inflowing tube has numerous very small openings at the end, while the outflowing tube is provided with one very large opening at its extremity. The inflowing tube thus effects a good douche, while the outflowing branch permits the water to return easily. Such an apparatus undoubtedly admits of a thorough douching of the stomach. The double-current tube, however, has the disadvantage that its size is quite considerable, and its introduction into the stomach of the patient is not very convenient.

In order to have an apparatus which could be introduced without any inconvenience, and which would at the same time allow a thorough douching of the stomach, I have constructed a new gastric douche. Its principle is based upon a valve arrangement. The apparatus consists of a rubber tube, not too flexible (thickness three-eighths of an inch, length twenty-six inches), at the end of which a hard-rubber capsule is attached (Fig. 1). The latter contains numerous very small openings all around, and one very large opening at its lower extremity. Within the capsule, which can be screwed apart, lies a small aluminum ball. This moves easily and freely within the capsule, and when it lies above the lower opening it entirely occludes the same. Two cross bars in the capsule prevent the entrance of the small ball into the tube (Fig. 2). If the tube described is attached to an irrigator provided

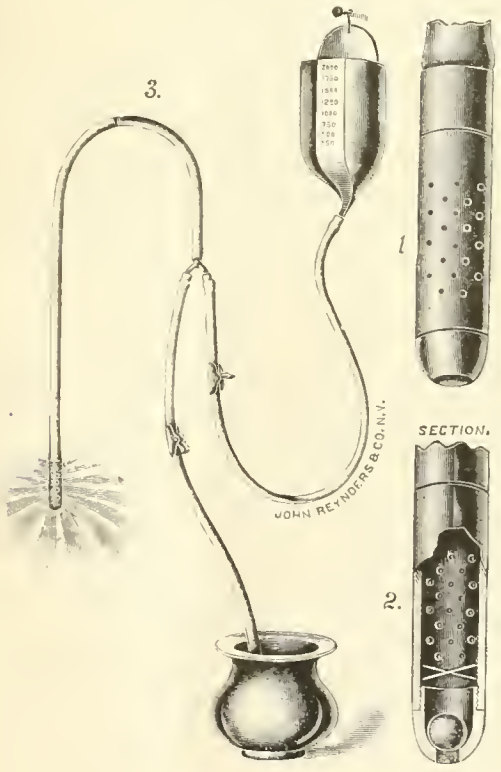
[8] Turck, Fenton B. "Recurrent Gastric Needle Spray or Douche." Cited from Hemmeter, "Diseases of the Stomach," p. 287.

with a waste pipe the apparatus is complete. If the waste pipe is closed, and the water made to run through the douche, the liquid will press the ball downward, thus closing up the large opening. The water will then come out through the small side openings like a very fine shower, sprinkling over quite a large area (Fig. 3). The inflowing tube being closed, and the waste pipe opened while the capsule is inserted into the liquid, the latter will push the ball upward, and thus the large opening will be free, and the water will easily return through it. The liquid will certainly return not only through the large opening, but also through the numerous small side openings. While these, however, do not admit the return of coarse particles, the latter will easily be able to pass through the large hole.

Method of using: The douche end of the apparatus is dipped into warm water, and then inserted into the stomach. It is necessary to pay attention that the capsule lies immediately below the cardia, and is not situated deeply in the stomach. The length of tubing from the mouth should be sixteen and one-half to seventeen inches. It may be useful to make a mark at this point of the tube. The tube is now attached to the irrigator, the outflowing pipe closed, the inflowing one opened, and the stomach sprinkled with about a quart of water. In order to make the water return from the stomach, the tube is inserted a little farther into the stomach, about four to six inches, the outflowing pipe opened, and the inflowing one closed. The liquid from within the stomach now returns. This procedure may be repeated three to four times. The temperature of the water should be regulated according to the therapeutic indications. The douche may also be connected with two irrigators, one containing



cold, the other warm water; the stomach may thus be sprinkled alternately with cold and warm water.

I have used the above-described gastric douche since the beginning of this year in many cases, and can say that it can be applied without any difficulty, and works well. I therefore do not hesitate to recommend it for general use in douching the stomach.

20 East Sixty-third Street.

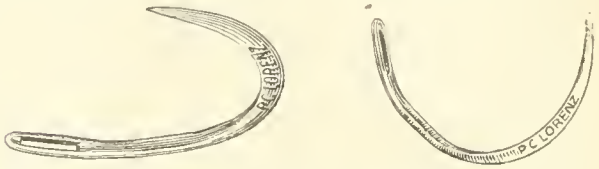
## AN IMPROVED NEEDLE.

By GEORGE GRAY WARD, Jr., M.D.,

NEW YORK,

ADJUNCT PROFESSOR OF GYNÆCOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL; INSTRUCTOR IN OBSTETRICS, CORNELL UNIVERSITY MEDICAL COLLEGE; ASSISTANT ATTENDING PHYSICIAN, MOTHERS AND BABIES' HOSPITAL.

All operators are acquainted with the aggravation of having a curved needle turn in the grasp of the needle-holder, especially when operating high up in the vagina or in the bottom of the pelvic cavity, at a critical



stage of the operation; also with the tendency of a needle of full curve to break when gripped too strongly with the holder. I have endeavored to overcome these difficulties by devising a needle which, while in its general shape a full curve, is perfectly straight at the junction of the middle third with the heel, so that the jaws of the needle-holder grasping the needle at this point exert equal pressure on both the upper and lower surface of the needle, instead of having to bear upon a concave surface above and a convex one below, as is the case with ordinary full-curved needles, and which is the cause of the frequent breaking.

To overcome the tendency of the needle to turn, it is made of a rectangular shape at the point of grasp, the upper and lower surfaces being perfectly flat and at right angles to the sides.

The point of the needle is made in two styles, that of the familiar Hagedorn and of the trocar. They can be used with any form of needle-holder. In practice they have fulfilled all my expectations.

230 West Fifty-ninth Street.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 25, 1899:

| | Cases | Deaths. |
|---|---|---|
| Tuberculosis | 183 | 149 |
| Typhoid fever | 52 | 10 |
| Scarlet fever | 163 | 9 |
| Measles | 291 | 12 |
| Diphtheria | 269 | 31 |
| Laryngeal diphtheria (croup) | 10 | 5 |
| Cerebro-spinal meningitis | 0 | 4 |
| Chicken-pox | 25 | 0 |

**Powdered Sugar** is said to possess decidedly inferior sweetening properties to those of the coarsely crystallized article. In the process of pulverization it is claimed that the heat and electricity produced transform a certain proportion of the sugar into glucose, whose sweetening powers are two and a half times less than those of saccharose.

**The Cleanly Japs.**—In the neighborhood of Matsumoto an off-day for rest can nowhere be more agreeably spent than at the delightful thermal springs of Asama-no-Yu. Indeed, I am free to own that such places, with their variety of situation and style, are among the pleasantest accessories to mountaineering in Central Japan. Whatever may be the character of

the establishment that has grown up around these natural hot baths, whose waters are credited with such marvellous therapeutic powers by the simple country folk who flock to them, it is certainly very refreshing after some days' hard scrambling to spend a quiet week and relax one's stiffened limbs in the grateful warmth of the Onsen, the sulphur bath. Sometimes, as here, one finds accommodation at a comfortable inn on the outskirts of a busy plain. Sometimes it is a group of chalets in the heart of the Alps, where a secluded valley is shut in by precipitous tree-clad mountain sides. Or, more quaint and curious still, you find yourself the first foreign traveller sharing a rude shanty with a party of rustics far up the side of some tall peak, where the customs of the bathers are primitive in the extreme. The Japanese value baths to an extraordinary extent. In one out-of-the-way place I know of they will stay in for a month at a time, and sit with large stones on their knees to keep them from floating or "turning turtle" in their sleep.—From "The Land of the Rising Sun," in *Fireside*.

**Advantages of Spectacles.**—Dr. Frankland always wore spectacles. One day on Ludgate Hill a porter passing him was nearly pushed off the pavement by an unintentional motion of the doctor. The fellow with characteristic insolence exclaimed, "Damn your spectacles." Frankland smiling observed, "It is not the first time they have saved my eyes."—*Sanitarian*.

**Lady Randolph Churchill to the Front.**—Lady Randolph Churchill, who is the prime mover and general manager of the American women's scheme for equipping and supplying with physicians and nurses the hospital ship *Maine* for aid to the British wounded in South Africa, on being interviewed, had this to say: "There is but one motive, one reason for the project of sending a hospital ship to the Cape. We have had oratory and societies for the promotion of Anglo-Saxon friendship. This is the golden opportunity to put that expression of good-will into tangible form. It is especially the province of American women to promote this cause, and it is woman's function to foster and nourish the suffering. American people are more adept at it, we believe, than any others. The *Maine* is to be essentially an American women's ship. We are not only to aid the wounded, but are to show the world that American women can do that good work better than any one else can do it. I am going to the Cape in the *Maine*, not because my son is there, for he will be one thousand miles away, but because I want the generous efforts of American contributors to be carried out under the personal supervision of a member of the executive committee. I am going because I think I can prevent any kind of friction between the American nurses whom Mrs. Whitelaw Reid is sending out and the British officials."

**Plea for the Employment of Skilled Surgeons in South Africa.**—An influential British journal says: "The great number of the wounded in South Africa, and the serious nature of the injuries from which so many of them are suffering, must throw an undue, almost a breaking strain upon the members of the R. A. M. C. In many families in England the anxiety about the condition of the wounded is intense. Should not our government at once obtain the services of, say, a dozen highly skilled surgeons of senior rank from the great hospitals of London, Edinburgh, and Dublin, and send them to South Africa? There are many injuries of the head and abdomen which can alone be successfully treated by surgeons of the greatest operative skill and of the widest experience and learning. This course was followed in the Franco-German war, when such men as von Langenbeck, Burghard, and others gave their services, and in the American-Spanish war, at which Senn, Nancrede, and several more experienced and skilful surgeons supervised operations, and acted as consultants."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 24, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |
| Illinois, Chicago | November 11th to 18th | 3 | |
| Kentucky, Louisville | November 8th to 16th | 1 | |
| Louisiana, New Orleans | November 11th to 18th | 1 | |
| Massachusetts, Chelsea | November 7th to 14th | 3 | |
| Ohio, Cleveland | November 11th to 18th | 1 | |
| Virginia, Portsmouth | November 11th to 18th | 3 | 2 |
| Washington, Seattle | October 7th to November 4th | 5 | |
| **Smallpox—Foreign.** | | | |
| Belgium, Antwerp | October 21st to 28th | 5 | |
| Austria, Bohemia Prague | October 21st to 28th | 9 | |
| England, Bedford | October 28th to November 4th | 1 | |
| Gibraltar, Gibraltar | October 22d to November 4th | 2 | |
| Greece, Athens | October 22d to November 4th | 7 | 2 |
| India, Bombay | October 1st to 24th | | 9 |
| Madras | October 14th to 20th | | 1 |
| Italy, Messina | October 28th to November 4th | | 1 |
| Japan, Osaka and Hiogo | October 1st to 14th | 1 | |
| Mexico, Chihuahua | November 4th to 11th | 11 | |
| Vera Cruz | November 2d to 9th | 7 | |
| Russia, Odessa | October 22d to 28th | 9 | 2 |
| St. Petersburg | October 2d to November 4th | 27 | 5 |
| Warsaw | October 16th to 22d | | 7 |
| Straits Settlements, Singapore | September 23d to August 7th | | 5 |
| Turkey, Constantinople | October 31st to November 6th | 1 | |
| **Yellow Fever—United States.** | | | |
| Florida, Key West | November 11th to 20th | 2 | 2 |
| Miami | November 15th to 22d | 25 | 2 |
| **Yellow Fever—Foreign.** | | | |
| Brazil, Bahia | Octobes 18th to 22d | 1 | 1 |
| Colombia, Barranquilla | October 22d to 28th | 1 | 1 |
| Cuba, Havana | November 4th to 11th | | 5 |
| Nuevitas | November 14th | * | |
| Mexico, Vera Cruz | November 2d to 9th | 4 | 3 |
| * One death on United States transport *Ingalls*. | | | |
| **Cholera.** | | | |
| India, Bombay | October 17th to 24th | | 1 |
| Japan, Osaka and Hiogo | October 7th to 14th | 1 | |
| **Plague—United States.** | | | |
| New York quarantine November 18th, one suspect—death on British steamship *J. R. Taylor*, from Santos. At sea, two suspected cases on board. | | | |
| **Plague—Foreign.** | | | |
| Brazil, Santos | October 22d to November 17th | 23 | 10 |
| Sao Paulo | October 17th to November 17th | 2 | |
| England, Plymouth | October 9th | * | |
| India, Bombay | October 10th to 24th | | 188 |
| * One case on steamship *Peninsular* from Bombay. | | | |

## Books Received.

### ELECTROSTATIC CURRENTS AND THE CURE OF LOCOMOTOR ATAXIA, RHEUMATOID ARTHRITIS, NEURITIS, MIGRAINE, INCONTINENCE OF URINE, SEXUAL IMPOTENCE, AND UTERINE FIBROIDS.[1]

BY WILLIAM JAMES MORTON, M.D.,

NEW YORK,

PROFESSOR OF NERVOUS AND MENTAL DISEASES AND ELECTROTHERAPEUTICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE agreeable duty of reading in my turn a paper before this society, individually engaged in so many special directions of work, has led me to choose from my own branch a certain new line of investigation of my own in electrotherapeutics, which I cannot but believe marks a distinct advance, and which may, I trust, prove of interest.

In 1734 the Abbé Nollet, of France, administered the first spark to a human being with a therapeutic purpose in mind. Thence sprang up the treatment of various diseases with frictional or so-called static electricity, by the direct application of the spark to the patient's person. The practice had its phases of vogue and of disuse until, in 1879, Professor Charcot revived its use in his famous clinic of the Salpêtrière.

In 1880 I had the good fortune to be one of Professor Charcot's pupils. The electrostatic treatment took a strong hold upon my imagination and my judgment. I bought two influence machines and a complete outfit of electrodes, and brought them home to this country, and in March, 1881, read a lengthy paper and exhibited the machines and outfit before the New York Academy of Medicine. At that time there was not a single influence machine in existence in this country in medical circles, nor scarcely, if at all, in scientific laboratories. The single-plate frictional machine did service for the pure scientist, while in medicine statical electricity therapeutically was practically unknown.

Thus at the New York Academy of Medicine, in 1881, began the epoch of electrostatic therapeutics in this country. To-day influence machines may be counted by the thousand in the land. Thousands of physicians' offices are equipped with them, and day by day not alone does their number increase, but also the scope of their application in the cure of disease. Is this folly? By no means. A great therapeutic truth lies in the electrostatic currents. The year's fashionable drugs come and fade like a line of spectres, but the electrostatic machine stays with us. It has come to stay.

I found in 1880 the statical electricity machine, a machine whose output was solely sparks, whether in its abstractly scientific uses or in its medical uses. I made it a machine whose output was also currents. In other words, I found it a machine whose output was a single electrical impulse; I made it a machine whose single electrical impulses and sparks could be employed in slow or rapid series as a potential variator to produce a current in any other part of the circuit. Hence to-day we have two epochs in the history and the uses of electrostatic apparatus and machines: (1) the period of the spark, from 1734 to 1880; (2) the period of the spark and of spark-gap currents, from 1880 to the present date.

I will ask your attention to-night, therefore, to (1) electrostatic treatment by sparks (Abbé Nollet); (2) electrostatic treatment by spark-gap currents (the writer).

1. Sparks.—Owing to its familiarity, I forbear detailed mention of the spark treatment. Briefly, a single long, "clean" spark is given with the ball electrode at its greatest practical working distance from the body, or a fine, prickling, "frictional" spark is administered by rubbing the electrode over the clothed skin. The long, clean spark is percussive; the percussion effect is produced not only upon the surface of the body, but within the tissue. I have termed the effect within tissue as "perturbatory." This perturbation effect within tissue produces a temporary maladjustment of tissue particles, followed by a readjustment and a consequent reaction of tissue to its normal metabolic relations. We might term the effect molecular gymnastics. The frictional spark—its second form alluded to—is counter-irritative, and also produces ingoing peripheral nerve effects upon the repective nerve centres (Hodge and others).

2. Currents, namely, Spark-Gap Currents.—In my paper before the New York Academy of Medicine, in 1881, I demonstrated and described this class of currents. In a recent paper, read for me by Dr. Apostoli before the Société Française d'Electrothérapie, I augmented the scope of spark-gap currents by a description of a phase of them which has great practical value in electrotherapeutics. The first spark-gap current, that of 1880, I christened the "static induced current." It is now in universal use wherever static electricity is employed, and recognized in text-books, and therefore requires no further mention. The second current is as yet little known, but, to my mind, is the culmination of all that is best in statical electrotherapeutics, not alone because of its therapeutical qualities, but also because of the facility of its application. We will, for the present, term it the "electric wave current," for the reason that the patient's person is at the passage of each individual spark across the spark gap a source of departure of an electric or Hertzian wave into space. We may, for simplicity, call both currents "spark-gap currents," since the existence of the spark gap and its employment is the essential feature of my discovery.

It is, indeed, a remarkable fact, when one recalls the immense amount of attention that was bestowed upon statical electricity up to 1880, a period of about one hundred and fifty years, that currents derivable from a static or frictional or influence machine, or charged Leyden jar, or any form of electrostatic apparatus, had escaped observation. But such is the fact. There is no record that any electrostatic apparatus, up to that date, had ever been employed to produce physiological tetanus in contradistinction to the single con-

[1] Read before the New York Harvard Medical Society, November 25, 1899.

traction produced by the spark directly or indirectly applied.

My desire to-night is to present to this society the actual working methods of producing this new current, to compare it to the static induced current and the spark, to show some of its modes of application and some of its effect upon living tissue, and to detail briefly cases and forms of disease in which electrostatic applications are useful.

For comparison, I first exhibit the static induced current by application to the persons of various members of the society. (Here followed a practical demonstration.)

It will be noticed that the patient is within the direct circuit of serially discharging armatures of oppositely charged condensers, and that two electrodes must be used as in ordinary electric administrations.

I next exhibit the electric wave current. (Demonstrations.) Here the patient forms no part of a metallic circuit. His tissue is charged and discharged with great rapidity—a rapidity equalling the rapidity of the discharge at the spark gap. Electrically, his situation is, that he forms a part of a "displacement circuit" of Maxwell in contact with a terminal metallic electrode (indeed, is a part of it so far as he is an ordinary conductor likea metal). The electric current now exists only in the dielectric air and in the dielectric portions of the patient, while his conducting portions, subjected to variations of potential, exhibit physiological reactions of an electrical type, but differing in wide degree from those exhibited by other and familiar forms of electrization. The patient's entire person is now subjected to the electric waves at each impulse of the spark at the spark gap; say easily two hundred or three hundred waves per second.

**Physiological Effects.**—If we take any given muscle or neuro-muscular mechanism as a type of the effect produced, we find we have established a physiological tetanus of a character less painful for a given degree of muscular contraction or noticeable to the patient than by any known electrical current.

How, then, do electrostatic currents act and cure?

There is a local effect upon the part affected, whether nerve, muscle, brain, spinal cord, joint, or what not, and at the same time a general or constitutional effect. Both effects are capable of positive proof and have been fully proven. The constitutional building up and regeneration of the patient's health tend to secure permanency of the local cure. The local effect is undoubtedly due to the agitation or perturbation of the tissue; the constitutional effect consists of an acceleration of the combustion processes, in varying degrees. Professor d'Arsonval, of Paris, has shown by laboratory experiments on man and on the lower animals that the production of water, carbonic acid, and urea is increased from forty to fifty per cent. Professor Renzi[1] has shown that fifty per cent. more neutral sulphur, producing sulphuric acid, is oxidized, and that there is a decisive action upon the metabolism of the nuclein. The salient fact is that the metabolism of the patient is augmented, and, as a consequence, his nutrition is improved.

**Methods.**—If we consider the variety of electrostatic treatments outlined that have a distinct meaning and effect upon the patient, to say nothing of the other varieties of electrotherapeutics involved in so-called galvanism and faradism, we cannot wonder that an electrotherapeutist must stand aghast when the simple remark is made by the patient, "Oh, I have taken electricity." Indeed, many physicians entertain the same idea of unity of electricity in its medical applications. A parallel case would be of an electrical engineer who was told to apply it in his profession. He would reply: "Shall I use electricity to produce light and illuminate, or heat and warm things, or electrolysis and decompose things, or cataphoresis and cause things to merge one with the other, or to run motors and cause things to move, or what not?"

[1] Revue Internationale d'Électrothérapie, September, 1899.

Applications to Treatment. Cases and Diseases.

**Progressive Locomotor Ataxia.**—By electrostatical treatment we may in the first and second stages of this disease confidently claim to make of progressive locomotor ataxia arrested locomotor ataxia. The pains cease, the girdle sensation disappears, the bladder troubles no longer exist, the gait improves, the sexual power returns—in short, the progress of the disease is arrested, leaving the patient with remaining defects due to the already destroyed tissue. This may clearly be termed a cure of locomotor ataxia. I cite a few cases, eight in number, cured or whose pains and other definite symptoms had ceased up to the time when last heard from. In all cases distinct improvement is noted from the time of beginning treatment.

Case I.—J. H. McG——, aged thirty-one years; September 23, 1895. Symptoms: frequent attacks of lightning pains, absent knee jerk, girdle sensation, incontinence of urine, constipation. He cannot stand with the eyes closed. There is loss of sexual function. His gait is ataxic. He has pin-point pupils. Duration, nine months.

September 30th: He feels the floor or pavement and walks better.

October 28th: The incontinence of urine is much less, and he walks farther and better.

November 27th: No incontinence of urine is present.

November 29th: He had a slight attack of shooting pains, the first since treatment began.

January 3, 1896: There is no incontinence of urine.

October 26th: He resumed business and has no attacks of pain.

In November and December he had a slight attack of pain.

May 7, 1897: He has now had no pain attacks for five months, and none up to January, 1899, nearly two years later.

Case II.—J. H——, aged thirty-one years, March 29, 1895. The disease began one year ago. He has shooting pains in the legs, which are numb from the knees down. There is the Argyll-Robertson symptom of the eyes; knee jerk is absent. He cannot stand with the eyes closed.

July 19th: He walks better and farther, and has no pains.

August 5th: He walks several miles.

January 3, 1896: There are no further pains. He considers himself well. He has sawed and split a cord of wood, and promises to return if symptoms reappear.

Case III.—P. B——, aged thirty-eight years, August 29, 1894. The disease began five years ago. He was in bed two months. There are lightning pains, Argyll-Robertson pupils, ataxic gait, Romberg symptoms, and numb areas. The knee jerk is absent.

November 14th: He walks better and has less pain.

March 1, 1895: He can walk five or six blocks, while previously he could not walk at all.

March 30th: He had a pain attack.

November 4th: Sexual functions returned.

April 21, 1897: He remains free from all symptoms.

Case IV.—W. R. C——, aged thirty-eight years; July 7, 1897. The disease followed a railroad accident nine months ago. He has shooting pains, ataxic gait, contracted pupils, but accommodation is preserved; failure of eyesight, much inco-ordination of legs, and Romberg symptom. The knee jerk is absent. He has girdle sensation, incontinence of urine, and constipation.

September 10th: The incontinence of urine ceased and all active symptoms were ameliorated in severity.

December 29th: Pains are occasional and slight. The patient was lost sight of at this point, and could not continue treatment.

Case V.—F. G——, aged fifty-eight years, November 30, 1894. The disease began nine years ago, with prickling in the feet, then shooting pains; he now has ataxic gait, with absence of knee jerk; Argyll-Robertson pupils; he cannot stand with the eyes closed.

December 3d: Improvement.

December 12th: The pain attacks occurred only twice since treatment was begun; formerly they were very frequent.

March 12th: The patient could not come longer for treatment, but seldom had pain and resumed his occupation.

Case VI.—J. F——, aged fifty-seven years; November 25, 1895; typical locomotor ataxia. The patient entered the office with an excruciating attack of lightning pains. After twenty minutes' treatment he was completely relieved, showing the immediate effect of electricity. The patient took treatment only very seldom, and at last accounts was not cured, but was greatly relieved.

Case VII.—C. M. H——, aged forty-eight years; March 28, 1895. The patient has shooting pains in both legs, ataxic gait, inco-ordination, abolished knee jerk, slowness of urination, constipation, loss of sexual power, and optic-nerve atrophy. Pains occur every night. He was under treatment two months; the pains ceased after the first ten days of treatment. One year later he reports that the pains have but seldom recurred, but I have no history of his entire recovery.

Case VIII.—S. M. H——, aged seventy-seven years. The knee jerk was abolished. He has darting and shooting pains which he calls "cannon-ball pains," so great are the shock and terror of their invasion. He has frequent and distressing pain at brief intervals during the entire night, and every three or four minutes during the day. In addition to the further usual symptoms, a symptom most marked is a profound anæsthesia from the waist downward, within which sensations of contact, temperature, and pain are abolished. He takes opium to relieve pain. A very interesting observation may be recorded here: Upon beginning treatment with the friction spark (ordinarily painful and creating a burning sensation) anywhere from the knees downward or in the gluteal and sacral regions, no sensation whatever was perceived by the patient; then suddenly at the expiration of four minutes the patient would exclaim, "There, you've fetched it!" and now the sensations were quite restored. The sensation of contact returned first, then that of temperature, then that of pain. The sensations thus restored remained restored a few hours, but were more easily regained at the next and at each successive treatment, until finally after a few weeks the restoration was perfect and continuous, and the patient can now walk much better and otherwise get his bearings.

This effect I have noticed in all cases in which there are anæsthetic and analgesic areas. In a case not here reported this improvement of itself, as well as that of the lightning pains, was a great satisfaction to the patient. The above-mentioned patient must be recorded as greatly improved, but it was probably impossible to cure him.

A patient, Mr. D——, was exhibited before the society, who had had locomotor ataxia for five years, and who on beginning treatment five weeks previously suffered from daily attacks of lightning pains. Answering a question of a member he stated that he had not had a single attack of pain since beginning treatment, could walk ten blocks where he couldn't walk one, and that he had reduced his morphine from six grains daily to none at all during the last three days.

**Rheumatoid Arthritis.**—This is commonly considered an incurable disease. But recently one of my instructors in the Post-Graduate Medical School and Hospital has collected from the records of the hospital and published[1] the results of the electrostatic treatment as pursued by me for many years, of upwards of thirty cases, in some of which a complete cure took place, and nearly all showed improvement to a point of an arrest of the morbid processes. Here also the active process may be arrested as in locomotor ataxia, leaving, of course, as in that disease, "remaining defects" due to prior tissue changes.

Since these thirty cases have been published I will not further refer to them here, but will add from my private notes two instances of complete cure of a severe and typical case of rheumatoid arthritis, and present one of the patients to you for your personal examination and questioning.

Case IX.—Miss J. B. F——, aged fifty years, September 4, 1895. The patient was engaged in severe literary occupation daily and subject to much anxiety. The disease began in January last, nine months ago. In February the metacarpo-phalangeal joints of both hands began to swell and were tender to the touch. This condition has steadily progressed to date. At the same time some of the corresponding joints in the feet swelled, and the disease soon extended to the wrists, shoulders, elbows, and knees. She took salicylic-acid treatment without benefit. She then went to Paris for treatment, and took vapor baths, these "broke her up" very much. In Paris she took electro-static treatment with marked benefit, and her physician there, Dr. ——, referred her to me in this country. Careful examination demonstrated that there could be no doubt of the diagnosis. The joints presented the usual rheumatoid arthritic contour with tenderness on pressure and restricted movements. They had never been hot or red. The patient wore large shoes and walked with difficulty. The disease was evidently in a stage prior to joint destruction, when the disease, as is frequently shown by an *x*-ray picture, is yet confined to the soft tissues. The patient was told that it might take a year to cure her. In September, 1896, one year from beginning treatment, she was quite recovered and has remained so ever since, in spite of most adverse circumstances of occupation and troubles. (This patient was exhibited to the members of the society, and the cure and diagnosis were confirmed.)

Case X.—Mrs. R. S. T——, aged thirty years. September 2, 1881; this was a case of characteristic arthritis deformans, located mainly in the right knee for six months, also somewhat in the left knee and in the joints of the fingers, wrist, and elbow. The patient had become a cripple and came to the office in a rolling-chair. The right knee was rigidly flexed at about a right angle; the joint was ankylosed and admitted of movement corresponding merely to about two inches of a segment of an arc described by the foot.

October 27th: Daily treatments were given. The area of pain, soreness, and swelling is reduced to a single central region. She has voluntary flexion of eight inches at the foot; forced flexion is increasing.

November 3d: Swelling in the joint increased today.

November 11th: There is an extensive puffed area to the left of the patella, but the knee permits of much freer motions.

At the end of three months the patient returned home cured. Dr. Jones, of St. Paul, whom I met in 1895, tells me the trouble never returned and that the

[1] The Post-Graduate, November, 1899, "Rheumatoid Arthritis," by Dr. W. B. Snow.

lady danced at the Assembly balls with her daughters. Later the patient called at my office and presented no signs whatever of ever having had rheumatoid arthritis. This case emphasizes the advantages of early treatment.

**Incontinence of Urine.**—CASE XI.—The patient, a Hebrew pedler, aged twenty-nine years, reports that all his life he has had almost nightly an escape of urine while in bed. This incontinence had become more troublesome than ever, and caused him to apply for relief. Electrostatic treatment was applied three times a week to the perineum, with the result that each week the loss was less or more infrequent, and ceased entirely at the end of three weeks. Later reports show that the cure was permanent.

I could add many cases of incontinence of urine in children, all cured by the same method. The electric wave current causes no pain, and hence is available with children, who generally have a fear of electricity.

**Sexual Impotence.**—The results in this class of cases are positive. Objectionable as this class of cases may be to report, a single case is justified as typical of many.

CASE XII.—J. S. C——, aged forty-six years; October 1st. His trouble began seven years ago with monthly emissions; these grew more frequent, until upon slight provocation they would occur many times a week and even in the daytime. He now has an average of four emissions a week. He then developed what he terms "internal emissions"; that is to say, complete erection without actual seminal emission, followed by profuse perspiration and exhaustion. (Probably the emission occurred backward.) He has severe pain in the back of the head and dull aches down his legs after such attacks. He wakes up exhausted in the morning, and now finds himself on any and all occasions completely impotent by reason of failure of erection.

November 4th: But one emission in three weeks; the "internal emission" ceased since the last four days. He sleeps well, eats well, and is gaining flesh; "head clearer" and is less nervous; the pains in the back of the head have ceased, and memory is improved.

December 15th: No more "internal emissions" occurred.

January 2d: He has had nine weeks' freedom from any emission; then one occurred.

March 1st: He had a successful coitus; in splendid health and is perfectly cured. Later reports show no relapse.

**Neuritis, Sciatic, Brachial, etc.**—In this disease electrostatic treatment is in truth specific, for no case in my hands has yet failed to be cured when sufficient and reasonable time is given. I do not give details, for I have recently published[1] 80 cases of this disease, in which my results were summed up as follows: Sciatica, 39 cases; axillary and brachial neuritis, 41 cases; total, 80. Average duration of treatment: sciatica, 32 days; axillary and brachial cases, 22 days. There was immediate relief from pain in all cases. Of the 80 cases, 57 were known to be permanently cured; 23 were relieved, so far as my records go; their ultimate history was not easily obtainable, but they are believed to have been cured.

**Migraine or "Sick Headache."**—CASE XIII.—Mrs. A. W. T——, aged thirty-nine years; November 14, 1895. During the last fifteen years she has lost at least a week out of each month with one of the most intense attacks of migraine I have ever seen, and now, although her menstrual periods have long since ceased, the disease has progressed until the headaches occur almost daily. The usual attack begins by a precursory sensation of feeling cold "like a clod of ice," especially "down the spine," and no amount of bed-covering or increased heat in the room will cause her to feel warm; at the same time she has a sinking, tired feeling and a "perfect goneness all over"; then begins a sharp pain in the right temple, "just as if a nail were being driven in," until the entire region of the right eye is involved; the sense of chilliness, faintness, and nervousness increases, and finally intense nausea supervenes with flatulence. Often a "blur" comes over the right eye, and she is now reduced to a condition in which she does not leave the house and is a continual sufferer. She "has tried everything" to get cured during her fifteen years of suffering, and is now discouraged, despondent, and so nervous that she starts at the slightest unexpected sound or movement, and does not trust herself to go out alone. The patient divides her attacks into "nail headaches" and ordinary sick headaches, the former being by far the most severe and most dreaded. She is much debilitated, with the usual symptoms of this condition. She began treatment.

November 16th: Severe headache.

November 26th: No headache to date, but nervous and prostrated.

November 28th: A slight attack.

December 4th: Headache to-day.

December 20th: No headache since last record, but experiences a dull feeling of "congestion in the head."

January 28, 1896: It is now two months since a "nail headache" has occurred. In this interval she has had several attempts at headache, which did not, however, culminate in an attack.

February 23d: It is now three months since she had a distinct attack. The patient has gained in weight, sleeps and eats well, and her chronic constipation has disappeared without other treatment than electricity. Her tongue, previously for the last three or four years "white-colored and lead-looking," is now red and normal.

May 18th: The patient's general appearance shows a remarkable change to health. She has gained weight. There is no further hemianopsia, nor "blurring sensations," before the eyes.

May 23d: She discontinued treatment, cured. I advised her to live out-doors all summer. She endured the fatigue of packing and departure without exhaustion.

Remarks: This patient was under treatment about six months. This I consider a short time to cure a migraine of fifteen years' standing. I may frankly say that the disease fought every step of the way, and that often both the patient and the doctor had reason to feel discouraged. But perseverance on the part of both won.

**Uterine Fibroid Tumor. Symptomatic Cure and One-Third Reduction of Mass.**—Finally I append a case of fibroid tumor treated by the electric-wave current, the first as yet reported.

CASE XIV.—Mrs. C. A. S——, aged forty-five years; April, 1899. A sister had a fibroid tumor, and was operated upon and died; hence the patient dreads operation in her own case. She first noticed her present illness ten years ago. She had abdominal cramps and other symptoms. Five years ago she had a good deal of hemorrhage. Three years ago she first noticed the presence of a tumor. She consulted with her family doctor, Dr. S——, who sent her to Dr. F——. He advised the removal of the tumor by surgical operation, because of the severe hemorrhage and the consequent drain upon her health. Friends advised seeing Dr. E——, who at first favored operation, but finally advised some delay. Later on she saw Dr. S—— and Dr. S——; the latter advised operation and removal of the tumor. She saw also

[1] William J. Morton, M.D.: "Cases of Sciatic and Brachial Neuritis and Neuralgia, Treatment and Cure by Electrostatic Currents." MEDICAL RECORD, April 15, 1899.

Dr. A——, who told her the tumor was the size of a seven-months' child.

Present symptoms. The tumor was fully of the size of a gravid uterus carrying a seventh-month child. Externally, through the abdominal walls, the mass was well-defined, round, and intensely hard; internally some parts of it pressed down deeply in the pelvic basin and were very hard to the touch. The patient experienced a distressing feeling of weight in her lower abdominal region, also at the same region "a burning feeling." She had much difficulty in urination; she could scarcely walk about, and in fact spent most of her time in bed. Her feet and ankles were often swollen. She felt a "pressure in her head," which she says made her feel as if she was going insane, and her eyesight became defective. But the most distressing symptom was the almost continuous hemorrhage. During the last three years, at the occurrence of each monthly period hemorrhage would continue from twelve days to three weeks out of each month, and frequently she was so weak that she could not raise her head. She had also frequent fainting spells.

Coming to me as a last resort, since she could not make up her mind to undergo a surgical operation, I felt justified in trying upon her the new electrostatic current, and that, too, wholly externally, since I had lost confidence to some extent in galvanism for these cases, and because, reasoning from analogy, this current ought, *a priori*, to set up a normal in place of a faulty nutrition in the parts acted upon. The patient has received about three treatments a week with the exception of during the summer. Omitting details of varying conditions, the patient to-day, November 5th, makes the following report: The feeling of weight, burning, and oppression in the pelvis has long since disappeared. Her feet no longer swell; urination is undisturbed, and she walks about everywhere and for a long time without discomfort. She is in splendid health, and, most important of all, she has had no hemorrhage since the first few weeks of treatment. The tumor, from being a heavy, solid, hard mass, has been reduced fully one-third in size, and upon its left-hand side has become quite soft to the touch both externally and internally. It is also more movable. In short, the symptomatic cure is perfect, while the tumor as a physical mass is also undergoing retrogression. In the mean time her menstruation has resumed a perfectly normal character, so that the results reported cannot be attributed to a cessation of menstrual activity. No medicines, or any other treatment, were employed. The progress would certainly have been more rapid if the treatment had been daily rather than tri-weekly, and possibly had it been internal rather than external. The patient is still under treatment, and she as well as her physician confidently expects a complete cure.

Several members of the society desired to examine this patient, and she kindly consented to meet Dr. Egbert H. Grandin and Dr. Charles Schram.

Dr. Grandin writes: "Unfortunately she is menstruating and I cannot examine her. The history you gave me is similar to that which I obtain from her."

Dr. Schram, after a careful examination and report upon the heart, writes: "In her present condition the insufficiency of the heart action would probably cause a laparotomy to be fatal."

I would here state that I have treated in the same manner and with immediate benefit other cases of menorrhagia than those associated with uterine fibroids, as well as cases of vaginitis, ovarian pain, ovarian tumor, etc.

To record cases further is impossible within the scope of this brief paper, whose primary object was to make a practical demonstration of a new method of treatment, namely, the electrostatic wave current, and this has led me naturally to include classes of cases in which the treatment is applicable.

Basing the statement upon a large clinical experience in my dispensary and private practice, I find the electrostatic-current treatment applicable with great efficacy, not only in the above-mentioned classes of cases of locomotor ataxia, rheumatoid arthritis, incontinence of urine, sexual impotence, neuritis and neuralgia, migraine and uterine fibroids, but also in ordinary rheumatism, acute, subacute, and chronic; in gout, in synovitis, in enlarged prostate, in anæmia and chlorosis, and especially also in neurasthenia and melancholia, and all conditions in which a state of general malnutrition exists.

---

## THE NATURE OF EXPERT TESTIMONY, AND THE DEFECTS IN THE METHODS BY WHICH IT IS NOW ADDUCED IN EVIDENCE.[1]

BY W. A. PURRINGTON,

COUNSELLOR AT LAW, NEW YORK.

MR. PRESIDENT, MEMBERS AND GUESTS OF THE ASSOCIATION: I trust you have noticed that to-night we are all giving unsworn testimony to our opinions upon one branch of opinion evidence. The other speakers are experts; I am but an ordinary witness. Therefore, if it were true that expert testimony is open to suspicion and less to be relied upon than that of ordinary men, this paper would be the most—instead of being, as it is, the least—valuable contribution to our discussion. Thus, by *reductio ad absurdum*, you are satisfied at the threshold of the inaccuracy of that premise.

You will not expect of me, in the half-hour allotted this paper, any very novel views upon that part of the subject allotted to me for dissection. It has been cut up and turned over many times. But every autopsy, even though badly done, may be useful; if not as a "bringer of new things," at least as a refresher of memory; and the end of this paper will be attained if it only helps to revivify your ancient knowledge.

There is undoubtedly widespread agreement that expert testimony as now given in legal proceedings is unsatisfactory, and equally widespread disagreement as to the method of making it satisfactory. In a way this is fortunate. If everything was perfect, or if we all agreed as to methods of remedying imperfections, no one could busy himself with reform; and, consequently, the ranks of the unemployed would be dangerously crowded. Life would become stale. We should not, for example, have had the pleasure of coming here this evening; or, if we had, then, as soon as my esteemed friend, Mr. Justice Bartlett, had read his thoughtful and interesting paper, the chorus would have cried, "Those are our views precisely," and we should have left this hall with that profound sense of loss experienced by good physicians and lawyers when a patient dies, or a cause is finally settled. We should have had one topic less to talk over in common, and to differ about.

Ordinarily diagnosis precedes treatment. Your programme to-night reverses this rule. We began with the remedies, leaving final diagnosis, as sometimes happens, to be made after the autopsy. It is for me only to examine the constitution and ailments of expert testimony, fully aware that my predecessors have done the same thing, in so far as they have followed the precedent of that unprincipled horse

[1] A paper read at the annual meeting of the New York State Medical Association at the New York Academy of Medicine, October 24, 1899, in conjunction with papers by Chief Justice Willard Bartlett, ex-Judge Joseph F. Daly, T. Charlton Lewis, Esq., and Theron A. Wales, M.D.

which, when the veterinary was about to treat him by insufflation, blew first.

Is it not paradoxical at least to say: "Expert testimony is less to be relied upon than that of ordinary witnesses or the conclusions drawn from the latter by average jurors"? Does not that seem equivalent to saying: "Inexperience is a more certain guide than experience; wisdom less to be depended upon than ignorance; trained thought a poorer reliance in its own field than unskilled conjecture"? Yet law reports are full of judicial opinions that all expert testimony is open to suspicion, to be received cautiously, and to be subordinated to testimony as to the "facts," so-called. Experts, as a class, are pronounced not only biassed but, by implication—yes, even in direct expression—dishonest.

In the old and ever-cited "Tracy Peerage Case" (10 Cl. and Fin., 154), Lord Campbell said that they come with such bias that hardly any weight can be given to their evidence. In a very recent case, Ferguson *vs.* Hubbell (97 N. Y., 507), Judge Earle, of our court of appeals, professing unwillingness to indorse the strong language of Lord Campbell, contented himself with this mild statement: "It is generally safer to take the judgments of unskilled jurors than the opinions of hired and generally biassed experts"; and most of us have smiled at the amusing, if cynical, classification of liars, wherein primacy of that interesting group is given to experts.

But text-books and essays have so fully cited the utterances of this sort, as well as others, more kindly, that it would waste time to recite them here. Let it be ours to inquire whether, on general principles, this extreme denunciation is justified, whether there is more truth in our legal paradox than in its medical counterpart, thus expressed by a brilliant essayist: "In science there are three unpardonable sins—trusting the senses, non-experts attempting to do the work of experts, and using deduction for induction, and vice versa."
